Perhaps an area of greatest unmet need is that of idiopathic dilated cardiomyopathy (DCM), a disorder afflicting approximately 2 million Americans, over a very broad age range (see Chapters 25 and 65). DCM is due to poorly characterized injuries to cardiac myocytes, with a variable degree of myocyte loss. In DCM, the heart exhibits increased levels of myocyte apoptosis, myocyte hypertrophy, and interstitial fibrosis. An important finding in this condition is preservation of intact reservoirs of CSCs; affected patients are therefore candidates for cell therapy with autologous preparations or therapies designed to promote endogenous stem/precursor cell recruitment. This hypothesis forms the basis for the ongoing POSEIDON-DCM trial, NCT01392625, which is currently enrolling patients (clinical trials.gov).

Disorders of Childhood/Congenital Heart Disease

Disorders of childhood are critical diseases in which cell therapy could address major unmet needs. Children with cardiomyopathy experience substantial morbidity and mortality, and the current approach to congenital heart diseases typically entails major surgical procedures. Regenerative strategies involving tissue valve regeneration and the construction of biologic patches have the potential to advance the treatment of childhood cardiac diseases. Experience with cell therapeutics for cardiomyopathy also may have substantial implications for managing childhood cardiomyopathies, including idiopathic DCM, myocarditis, and post-chemotherapy or radiation-induced cardiomyopathies.

Safety Profile of Cardiac Cell Therapy

The totality of evidence from the trials to date using various bone marrow cells for patients with acute MI or ischemic heart failure has revealed a remarkable safety profile. Notable concerns that have been raised include a risk for proarrhythmia, tumor or other ectopic tissue formation, risks related to delivery, and risks related to the cells migrating to unwanted locations. Remarkably, few of these concerns have appeared to materialize, particularly with regard to ectopic tissue formation or immunologic reactions. In a phase I trial of intravenous, allogeneic MSCs for acute MI, no increase in side effects such as tumor or ectopic tissue formation was observed, and a provocative finding in some cases was a decrease in pulmonary side effects and arrhythmias, suggesting a therapeutic effect.¹⁷

The relative success at this stage of investigation, certainly with regard to safety profile, has prompted the extrapolation of clinical testing to other areas of myocardial dysfunction and the quest for cell therapeutic products of potentially greater efficacy. Early-stage

clinical investigation is under way for second-generation cell products. As described earlier, these include MPCs, enhanced cardiopoietic stem cells, and cell combinations.

A Role for Embryonic Stem Cells and Inducible Pluripotent Stem Cells?

Using pluripotent stem cells for cardiac repair aims to achieve cell repopulation. In experimental models, embryonic stem cells (ESCs) and inducible pluripotent stem cells (iPS cells) robustly engraft and differentiate into cardiac myocytes. Of note, the success of the strategies, discussed earlier, that use adult stem cells and/or tissue-specific stem cells may obviate or reduce the need to use ESCs or iPS cells in a widespread manner therapeutically. An important use of these cells is for drug screening and for the development of patient-specific myocytes.⁴⁶

Directed Differentiation

Recently the notion of directed differentiation of host fibroblasts also has been demonstrated experimentally.^{47,48} This raises an interesting new strategy of stimulating cardiac repair by inducing the differentiation of endogenous cardiac fibroblasts into myocytes.

Summary and Future Perspectives for Cell Therapy

The past decade has witnessed extraordinary efforts to advance regenerative medicine in the cardiovascular area. Tremendous efforts have been expended to test the hypothesis that cell-based therapy may be effective to treat a panoply of cardiac disorders including acute MI, heart failure, hibernating myocardium, and chronic angina pectoris. The results at present are encouraging, albeit not as dramatic as envisioned by some investigators. Rapid advances have in fact been achieved in technologies for both cell processing and delivery strategies, the optimal combination of which will undoubtedly enhance the efficacy of the approach. Despite controversies, the field has advanced translationally to the point that multiple cell strategies are in phase II trials. The best of these approaches can be expected to be tested in pivotal trials for clinical efficacy within the next decade.

TISSUE ENGINEERING

Tissue engineering in its original conception aims at providing living tissue grafts that could be used to surgically repair or replace dead or congenitally defective myocardium. Constructs of heart muscle can be generated using cell populations seeded within a matrix scaffold to form three-dimensional engineered cardiac tissue. So far, it has been challenging to generate tissue *in vitro* with contractile force and size sufficient to support the failing heart.⁴⁹ Various culture conditions have been used in combination with multiple cell mixtures (e.g., neonatal cardiomyocytes, fibroblasts, skeletal myoblasts, adult stem cells and ESCs) for creating a range of patches, strips, loops, and chambers of beating myocardial tissue *in vitro*. Engraftment of engineered heart tissue from neonatal rat cardiomyocytes onto rat hearts after MI improved the contractile function and was shown to be electrically coupled to the native myocardium. ESCs and iPS cells, from animals and humans, are alternative sources for the generation of heart tissue *in vitro*, and although survival of human engineered heart tissue implanted in the rat has been demonstrated, maturation of the tissue phenotype is an important challenge, and engraftment followed by functional improvement in the human heart remain an ambitious goal. In addition, the size of typical avascular engineered heart tissue constructs is limited by oxygen diffusion. Accordingly, researchers have fused several individually cultured single engineered tissue rings or sheets, and various strategies are under development to create vascularized constructs that can be perfused and integrated with the host circulation.

At the interface between tissue engineering and cell therapy, the development of novel biomaterials has gained increasing interest

recently. Biodegradable matrix materials with sophisticated chemical and mechanical properties have been developed to be used as ventricular restraints and to provide scaffolds for *in vitro* tissue engineering.⁵⁰ In addition, the injection of new self-assembling nanomaterials and decellularized natural tissue matrix can adapt the intramyocardial cellular microenvironments to augment homing and functional integration of cells for *in situ* tissue engineering and subsequent cardiac regeneration and repair.

GENE THERAPY

Whereas the basis of cell therapy is to repopulate damaged areas within the heart with new cells, the basis of gene therapy is to repair the compromised cardiac myocytes in the failing heart. Through the expression of specific proteins or downregulating them, targeted gene transfer can rescue the function of cardiac cells *in vivo*.

Gene Therapy Vectors

The development of cardiovascular gene transfer intervention necessitates addressing several factors to ensure high efficiency while minimizing toxicity.⁵¹ These include understanding target cell and transgene biology, and the temporal and spatial patterns of the specific cardiovascular pathophysiological process. In addition, the choices of gene and vector delivery systems also critically determine clinical outcomes. Answering these questions will dictate the proportion of target cells within the myocardium that need to be successfully gene-modified in order to elicit cardioprotection. Restoring myocardial contractility in the context of heart failure requires the successful gene transfer to a vast majority of cardiac myocytes in the ventricular myocardium to enable a significant impact on ventricular function. Furthermore, the required temporal pattern of transgene expression will determine the choice of gene transfer system that can be employed for efficient and positive results. Gene delivery systems can be classified into two categories, nonviral systems and recombinant viral systems, with each having unique profiles in gene transfer expression, and advantages/disadvantages as shown in **Figure 30-5**. Nonviral vectors include naked plasmid DNA, liposomal DNA complexes, polymer-carried DNA, and oligonucleotides. Plasmids are double-stranded circular DNAs containing transgenes encoding proteins of interest, in addition to having enhancer and promoter sequences.⁵¹

Viral vectors from the family Retroviridae include retrovirus and lentivirus.⁵¹ Retroviruses contain single-stranded positive-sense RNA, which uses a virally encoded reverse transcriptase to generate double-stranded DNA. For viral DNA integration into the host cell genome, the host cell nuclear membrane must be broken down, as occurs during cell division; therefore retroviruses are limited to infecting dividing cells and cannot efficiently transduce most cardiomyocytes. Lentiviral vectors, also from the family Retroviridae, are single-stranded RNA viruses using reverse transcriptase and genome integration for long-term expression of transgenes.⁵¹ However, lentiviral vectors are capable of transducing mitotically quiescent cells, allowing for efficient transduction of cardiomyocytes. The random integration afforded by the lentivirus continues to be a concern.

Adenovirus is a nonenveloped, nonintegrating virus containing double-stranded DNA with two main transcriptional regions, early and late phase. Early phase encodes E1, E2, E3, and E4 viral proteins, which are necessary for activating the S phase of the cell cycle, DNA polymerase, and splicing proteins. The E1 to E4 proteins elicit a significant innate immune response, which is the major therapeutic challenge in using adenovirus in human applications. Third-generation "gutless" adenoviral vectors with E1 to E4 deleted have a lower immunogenicity profile, thereby partially overcoming this obstacle.⁵¹ In the heart, adenoviral transgene expression is robust yet transient. Transgene expression levels peak within 2 to 3 days but return to undetectable levels by 2 weeks. This limitation imposes therapeutic challenges for chronic pathologic processes such as congestive heart failure, but use of recombinant adenoviral vectors may be appropriate for the short-term expression of proangiogenic factors.

Adeno-associated viruses (AAVs) are members of the family Parvoviridae and are nonenveloped, single-stranded DNA viruses.⁵² AAVs are relatively small (20 nm) and therefore are limited in their genome

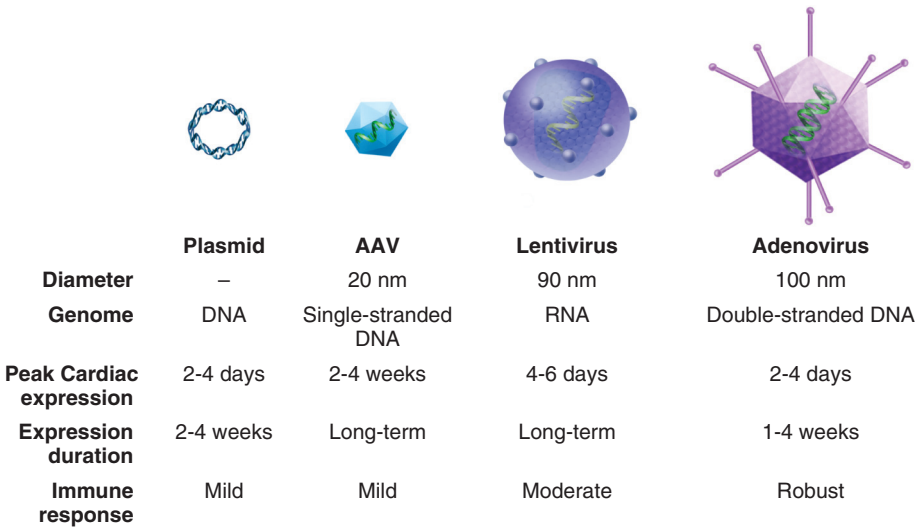

FIGURE 30-5 Viral vectors for cardiac gene transfer. Four different vector systems have been widely used in cardiac gene therapy: plasmids, adenoviruses, lentiviruses, and AAVs. Each of these viruses has specific characteristics, as summarized in the chart.

capacity of 4.7 kilobases. The 13 reported serotypes of AAV exhibit various degrees of tissue tropism, depending on capsid protein structure.⁵² AAV serotypes 1, 6, 8, and 9 have been identified as being the most cardiotropic; however, significant transduction in nontarget tissues such as liver, skeletal muscle, and lung persists. Neutralizing antibodies to various AAV serotypes are present in approximately 20% to 80% of the population, severely limiting potential therapeutic use of AAV, and constitute a major exclusion criterion in many AAV-based clinical trials.

The various vector systems all have different expression kinetics and tissue tropisms that must be taken into account in designing human gene therapy trials. Nonspecific expression and off-target effects are obstacles for any therapeutic modality.

Molecular Targets of Gene Therapy

The past 2 decades witnessed significant evolution in our understanding of the pathophysiology of heart failure in its molecular and cellular dimensions, thus broadening the scope of interventions available for gene therapy. For targets to be validated, it is important that they rescue function in animal models when heart failure has already been established, that the rescue is not associated with arrhythmogenesis, and that a gene-dose effect is established (i.e., with increasing gene expression, a concomitant improvement in function is observed). Excitation-contraction coupling is dysregulated at multiple levels in the development of heart failure. For this reason, the various channels, transporters, and critical proteins have been targeted pharmacologically and by genetic editing to restore contractile function. In **Figure 30-6**, the various targets in excitation-contraction coupling are depicted.

Targeting the β -Adrenergic System

The beta-adrenergic signaling is adversely affected by multiple changes that lead to beta-adrenergic receptor (β -AR) downregulation and desensitization (see **Chapters 21 and 22**). Upregulation of the critical protein G protein–coupled receptor kinase 2 (GRK2) has been linked to β -AR signaling abnormalities. Several gene-based experiments tested the hypothesis that genetic manipulation of the myocardial β -AR system can enhance cardiac function. Both direct and intracoronary myocardial delivery of adenovirus containing the human β 2-AR transgene have resulted in enhanced cardiac performance in rodents and mammalian models.⁵³

The interaction between activated β -ARs and G proteins is regulated by kinases that modulate the receptor activity through phosphorylation of its carboxyl terminus. Agonist-dependent desensitization is mediated by a family of G protein–coupled receptor

kinases (GRKs), which phosphorylate the agonist-occupied receptors, resulting in functional uncoupling. GRK2 binds to the $G\beta\gamma$ subunit of activated G proteins, phosphorylating β -ARs that subsequently attach to an inhibitory protein β -arrestin (see **Chapter 21**). β ARKct, a peptide capable of inhibiting GRK2-mediated β -AR desensitization, has been evaluated in vivo in animals. Using intracoronary adenovirus-mediated β ARKct transgene delivery to rabbits 3 weeks after induced MI, a marked reversal of ventricular dysfunction was achieved.⁵⁴

Although detrimental outcomes were demonstrated with multiple elements of the beta-adrenergic system used to improve the expression of cyclic adenosine monophosphate (cAMP), activation of adenylyl cyclase (AC) type VI (AC VI) seems to have a unique favorable profile. Overexpression of AC VI in transgenic mice resulted in improved cardiac function in response to adrenergic stimulation, along with increased cAMP production in isolated cardiac myocytes. Of importance, AC VI had a neutral effect on

basal heart function and was not associated with any structural heart abnormalities. In a pacing model of heart failure in pigs, intracoronary delivery of adenovirus encoding AC VI resulted in improved left ventricular function and remodeling, associated with increased cAMP-generating capacity.⁵⁵ The favorable effects of AC VI in preclinical studies are encouraging, and this approach is currently under investigation for initiation of clinical trials in patients with heart failure.

Targeting Ca^{2+} Cycling Proteins.

Heart failure is characterized by multiple defects in Ca^{2+} -handling proteins involved in excitation-contraction coupling (see **Fig. 30-6**) (see **Chapters 21 and 22**). Reversal of those defects by gene therapy techniques has shown very promising results. More than 20 years ago, Gwathmey and associates first reported that calcium cycling is abnormal in human heart failure⁵⁶ and that this abnormality was due in part to decreased SERCA2a (sarcoplasmic reticulum Ca^{2+} -ATPase type 2a) activity regardless of the etiology of the heart failure.⁵⁷ Improvement in cardiac contractility after SERCA2a gene transfer has been demonstrated in a large number of experimental models of heart failure.⁵⁸ More important, long-term overexpression of SERCA2a by intracoronary delivery of AAV carrying SERCA2a has been associated with preserved systolic function and improved ventricular remodeling in a swine volume-overload model of heart failure.⁵⁷ Beyond its effects on enhancing contractility, SERCA2a gene transfer has been shown to restore the energetics state of the heart in terms of both energy supply and utilization, decrease ventricular arrhythmias,⁵⁷ and enhance coronary flow through activation of nitric oxide synthase (NOS) in endothelial cells (i.e., eNOS).⁵⁷ One concern with refilling the sarcoplasmic reticulum with Ca^{2+} in the setting of a leaky ryanodine receptor has been the possibility of inducing ventricular arrhythmias. Multiple studies have in fact now shown that SERCA2a gene transfer decreases the incidence of ventricular arrhythmias in the setting of heart failure models, improves arrhythmogenic substrate, and limits triggers.⁵⁹

Another approach to improve Ca^{2+} handling involves inhibition of phospholamban (PLN) (see **Chapter 21**). Decreasing PLN in human cardiac myocytes showed an improvement in contraction and relaxation velocities similar to the benefit seen with SERCA2a gene transfer. Silencing of PLN expression in a sheep heart failure model resulted in improved SERCA activity along with improved systolic and diastolic left ventricular function.⁵⁷ In addition to the aforementioned conventional gene therapy strategies, RNA interference (RNAi) therapy (i.e., post-transcriptional gene silencing) was used in a rodent model of heart failure, in an attempt to suppress PLN expression. AAV9-RNAi vector generated stable cardiac production of a regulatory RNA sequence, which in turn suppressed PLN expression. SERCA2a protein was subsequently increased, accompanied by restoration of systolic and diastolic cardiac function.⁶⁰

Heart failure also is associated with elevated protein phosphatase 1 activity in humans, resulting in dephosphorylation of PLN.

FIGURE 30-6 Excitation-contraction coupling in cardiac myocytes provides multiple targets for gene therapy. AC = adenylyl cyclase; AngIII = angiotensin III; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; DAG = diacylglycerol; ET-1 = endothelin-1; FKB = FK506 binding protein; GRK2 = G protein-coupled receptor kinase 2; IP3 = inositol triphosphate; NE = norepinephrine; PDE = phosphodiesterase; PKA = protein kinase A; PLC = phospholipase C; PP1 = protein phosphatase 1; PP1-I = inhibitor 1 of protein phosphatase 1; RyR = ryanodine receptor; SERCA2a = sarcoplasmic reticulum Ca²⁺-ATPase type 2a; S100A1 = S100 calcium-binding protein A1.

Overexpression of PP1 in mice has been associated with decreased β-AR-mediated contractile responses, depressed cardiac function, and premature death consistent with heart failure.⁶¹ In mammalian myocardium, the endogenous protein inhibitor 1 (I-1) directly inhibits protein phosphatase 1 (PP1) activity. Expression of a constitutively active I-1 in transgenic mice led to PP1 inhibition, with increased phosphorylation of PLN and enhanced cardiac contractility.⁶¹ A recent study in a large animal model of heart failure induced by ischemic injury showed that AAV9 overexpressing a constitutively active form of I-1 (I-1c) results in long-term improved contractile function.⁶¹

S100 is part of a family of Ca²⁺-modulated proteins implicated in intracellular regulatory activities. S100A1 is the most abundant S100 protein isoform in the heart. It promotes cardiac contractile and relaxation function through enhancing the activity of both ryanodine receptors and SERCA2a.⁶² AAV9 gene transfer of S100A1 in a preclinical model of ischemic cardiomyopathy induced significant improvements in contractile function reinforcing the rationale that a clinical trial of S100A1 gene therapy for human heart failure should be forthcoming.⁶²

Recently Kho and colleagues reported that the levels and activity of SERCA2a in cardiomyocytes are modulated in parallel with the levels of the small ubiquitin-like modifier type 1 (SUMO1).⁶³ SUMOs are a

family of peptides that broadly alter the function of other proteins in cells through a post-translational modification known as sumoylation. Kho's group found that sumoylation enhanced the stability of SERCA2a in the cell, as well as increasing its activity. SUMO1 levels were reduced in murine and pig models of heart failure and in failing human ventricles. Increasing SUMO1 levels by AAV9 gene transfer led to a restoration of SERCA2a levels, improved hemodynamic performance, and reduced mortality among the animals with heart failure.

Homing of Stem Cells

As mentioned earlier, when the heart tissue is damaged by an ischemic insult, cardiac progenitor cells are recruited to the injury site to aid repair. It is all too clear, however, from the number of heart attack survivors suffering from hypertrophy and heart failure, that this repair process is limited. A number of endogenous factors have been shown to enhance stem cell mobilization to the injury area. One such factor, stem cell factor (SCF), is the ligand for the cell surface receptor c-kit, expressed on progenitor cells, and it both recruits progenitor cells and promotes their proliferation. After gene transfer of SCF in

experimental models of myocardial ischemia, hearts exhibited decreased fibrosis, less left ventricular hypertrophy, and, of importance, improved function.⁶⁴ SCF-overexpressing hearts had recruited higher numbers of progenitor cells and survived longer. The stromal cell–derived factor-1 (SDF-1)-CXCR4 complex is another factor and has emerged as a therapeutic target in ischemic heart failure, owing to the ability of the SDF-1–CXCR4 system to promote the homing of stem cells to injured areas of the myocardium.⁶⁵

Cell and Gene Delivery Systems

The list of catheter technologies for delivering biologic agents directly to the myocardium continues to expand.⁶⁶ The ability to appropriately target the heart with the therapeutic agents and the characteristics of the delivery system play a key role in the success of the approach. Indeed, needle characteristics may play a crucial role in cell retention. Various routes of administration have used the coronary and ventricular anatomy of the human heart. Intracoronary infusion of the biologic agents in selective coronary arteries, with and without occlusion, has been used in clinical trials⁶⁶ (Fig. 30-7). In addition, retrograde infusion through the coronary sinuses has been tested mainly in preclinical settings with various degrees of success. Direct myocardial injections using surgical or catheter-based techniques are being tested in a number of clinical trials (Fig. 30-8). The catheter-based ventricular injections are enhanced by electromechanical mapping systems. Finally, pericardial injection of the biologic agents also has been tested in animal models, but their efficacy has not been confirmed (see Fig. 30-8).

Clinical Trials in Gene Therapy

After years of consecutive failures, gene therapy trials for specific monogenic diseases have shown some successes, most notably for inherited blindness in a pediatric patient with Leber's congenital amaurosis, and in hemophilia.⁶⁶

The first clinical trial of gene therapy in patients with heart failure was launched in the United States in 2007. CUPID (Calcium Up-Regulation by Percutaneous Administration of Gene Therapy in Cardiac Disease) is a multicenter trial designed to evaluate the safety

profile and the biologic effects of gene transfer of the SERCA2a complementary DNA (cDNA) by delivering a recombinant AAV1 (AAV1.SERCA2a) in patients with advanced heart failure.⁶⁶ This phase I trial in 12 advanced heart failure patients treated with one of four-dose cohorts of AAV1.SERCA2a established preliminary safety, which led to a phase II randomized, double-blind, placebo-controlled trial. In the phase II study, the effectiveness of three different dose cohorts of AAV1.SERCA2a (low dose: 6×10^{11} DRP [DNase-resistant particles]; middle dose: 3×10^{12} DRP; and high dose: 1×10^{13} DRP) versus placebo was evaluated in 39 patients with advanced heart failure. At 12 months of follow-up, in comparison with the placebo group, the high-dose group exhibited reduced signs and symptoms of HF and improved functional status, biomarker profile, and left ventricular function. A significant decrease in cardiovascular events (hospitalizations related to heart failure, episodes of worsening heart failure, death or the requirement for left ventricular assist devices or cardiac transplantation) was evident in the patients who received high-dose AAV1.SERCA2a compared with those who received placebo, as shown in Figure 30-9. No increases in adverse events, disease-related events, laboratory abnormalities, or arrhythmias were observed in AAV1.SERCA2a-treated patients compared with those in the placebo group.⁶⁷ Additional clinical studies are now under way, including an international study in 250 patients (randomly assigned to receive treatment or placebo in a 1:1 ratio) testing whether use of AAV1.SERCA2a at a dose of 1×10^{13} DRP is an effective therapy to reduce clinical events in advanced heart failure (NCT01643330).

Two other clinical trials targeting SERCA2a are currently enrolling patients. The first trial is in patients with advanced heart failure who received left ventricular assist devices at least 1 month before treatment and who will receive either AAV1.SERCA2a or saline. This trial is being conducted in the United Kingdom (NCT00534703). The second trial is a double blind, randomized, placebo-controlled study at the Pitié-Salpêtrière Hospital in Paris, with the primary objective to investigate the impact of AAV1.SERCA2a on cardiac remodeling parameters in patients with severe heart failure (NCT01966887).

In a separate clinical study sponsored by the U.S. Department of Veterans Affairs and the National Institutes of Health (NIH), adenovirus-5 encoding human AC VI is being delivered by intracoronary injection to patients with congestive heart failure (NCT00787059). The primary efficacy endpoints are a composite of changes in exercise treadmill time, in left ventricular function by echocardiography before and during dobutamine infusion, and in the rate of left ventricular pressure development and decline (dP/dt and -dP/dt) before and during dobutamine infusion.

An additional trial⁶⁵ has examined the effects of injecting SDF-1 directly into the myocardium of patients with ischemic heart disease (NCT01082094). An open-label dose escalation study was performed to evaluate the safety of a single dose of SDF-1 administered by endomyocardial injection to cohorts of adults with ischemic cardiomyopathy received any of three different doses of SDF-1: 5, 15, or 30 mg, given by endomyocardial injection. The patients were followed for 12 months with assessment of several clinical outcomes. Endomyocardial administration of SDF-1 was found to be feasible and safe.⁶⁵ Although this phase I trial was designed primarily to assess the safety of the approach in humans, patients receiving the highest doses (15 and 30 mg) were found to have an improvement in clinical status, as reflected in quality of life, 6-minute walk distance, and New York Heart Association (NYHA) class.⁶⁵

FIGURE 30-7 **A**, Coronary artery infusion: The vector is injected through a catheter without interruption of the coronary flow using a slow infusion. **B**, Retrograde coronary venous infusion with simultaneous blocking of a coronary artery and a coronary vein: The vector is injected into a coronary vein and resides in the coronary circulation until both balloons are deflated.

FIGURE 30-8 Direct myocardial injection and pericardial injection. **A**, Percutaneous myocardial injection. The vector is delivered through an injection catheter using an endocardial approach. **B**, Surgical myocardial injection. The vector is delivered using an epicardial approach. **C**, Percutaneous pericardial injection.

FIGURE 30-9 Cumulative clinical event rates adjusted for competing risk of terminal events in the phase II CUPID trial in patients with severe heart failure who received intracoronary injections of (1) saline, (2) low-dose AAV1.SERCA2a, (3) mid-dose AAV1.SERCA2a, or (4) higher-dose AAV1.SERCA2a injections. The patients were followed for 12 months. (From Jessup M, Greenberg B, Mancini D, et al: Calcium Upregulation by Percutaneous Administration of Gene Therapy in Cardiac Disease (CUPID): a phase 2 trial of intracoronary gene therapy of sarcoplasmic reticulum Ca²⁺-ATPase in patients with advanced heart failure. *Circulation* 124:304, 2011.)

Summary and Future Perspectives for Gene Therapy

As our understanding of the molecular mechanisms associated with heart failure has improved and vectors with cardiotropic properties are being developed, gene therapy can now be considered as a viable adjunctive treatment to mechanical and pharmacologic therapies for heart failure. In the coming years, more targets will emerge that are amenable to genetic manipulations, along with more advanced vector systems, which will undoubtedly lead to safer and more effective clinical trials in gene therapy for heart failure.

Cell and gene therapeutic strategies are currently emerging as promising new approaches to fundamentally alter the structure and function of the diseased heart. Both strategies have significant experimental support underlying their application, and the accumulating clinical trial data support their safety and potential efficacy.

These approaches are important because they address fundamental issues of disease pathophysiology not addressed by current therapeutics. Developments in these strategies have the potential to have a major impact in patient management in the future.

Advanced heart failure, defined as significant symptoms, end-organ compromise, or severe functional limitation from heart failure despite optimal medical and device therapy,¹ develops in an uncertain number of persons with heart failure. Increasing numbers of persons surviving to late life, when heart failure is more common, and continuing improvement in the management of early cardiovascular illness suggest that advanced heart failure will be increasingly common in the practice of cardiology. Because 80% of persons with heart failure are older than 65 years and heart failure is most prevalent in persons older than 80, the heart failure syndrome commonly develops in the context of other medical and functional problems. Clinicians will be frequently challenged to manage advanced heart failure in the setting of both interrelated illnesses such as diabetes and kidney disease and coexisting conditions such as pulmonary hypertension, cognitive impairment, and frailty. This chapter discusses the ethics and practical aspects of management of advanced heart failure.

PROGNOSTICATION AND PROBABLE COURSE OF ADVANCED HEART FAILURE

Young persons (<70 years) with heart failure are generally managed aggressively. In this population, a reduced ejection fraction from familial or ischemic cardiomyopathy predominates. Aggressive titration to maximal doses of beta blockers, medications to block the renin-angiotensin-aldosterone disarray of heart failure, and for some patients, implantation of a biventricular pacemaker for cardiac resynchronization therapy (CRT) will enhance function, improve symptoms from heart failure, and prolong life (see Chapters 25 and 26). Patients with a persistently reduced ejection fraction despite optimized medical therapy will receive an implantable cardioverter-defibrillator (ICD) for prophylaxis against sudden cardiac death.

Some young patients will be markedly ill despite the aforementioned therapies, and some will be eligible for urgent treatment with a left ventricular assist device (LVAD) or cardiac transplantation, if lucky, which will buy them several more years of life with improved function (see Chapters 28 and 29). In these very ill people, heart failure has a significant impact on their lives and those of their families. Patients and their families need support to cope with illness and the threat of life-ending illness. Even successful LVAD therapy or heart transplantation carries significant encumbrances and burdens. The threat of death still remains; LVAD may buy 2 to 8 years, and cardiac transplantation will buy, on average, 15 years before the patient requires additional interventions or dies.

Even when patients with heart failure improve with therapy, their lives are altered by coping with chronic illness. In addition to coping with lifestyle changes and chronic disability and symptoms, many patients

and their families live with uncertainty about their futures. Often, however, patients with chronic heart failure do not perceive their illness as life shortening.² Based on prognostic models, the life expectancy of people with chronic heart failure may be 10 to 20 years, although a small percentage die each year. Progression of heart failure or life-threatening deterioration may shock these patients and families who have not understood that heart failure shortens lives and leads to death. Ideally, early in the illness and at decision points throughout care, it is appropriate to allow all patients with heart failure and their families to know that such patients are at risk for death from progressive heart failure or sudden cardiac death. This information is best provided when discussing the goals of treatments to prolong life and to reduce the chance of sudden death because both these conversations require acknowledgement that people with heart failure die.

Predicting life expectancy or the probable course of a given patient with heart failure is difficult. Even with advanced heart failure, the prognosis for a specific patient is uncertain. Data from the COMPANION trial suggest that a quarter of people with advanced heart failure die of problems not related to their heart disease and that three quarters eventually die of progressive heart failure or sudden cardiac death.³ Predictive models can help identify approximate expected lengths of life for patients with advanced heart failure. However, the operative word is "approximate."

Some sudden death is avoided by ICD shock, but ICD shocks confer increased death rates over the subsequent year.⁴ The course to death varies following ICD implantation.⁵ For example, in an analysis of an Ontario database, heart failure patients receiving an ICD who were older than 70 years with two or more comorbid conditions had a 63% 2-year mortality rate, in contrast to 25% to 26% 2-year mortality in younger heart failure patients with two or more comorbid conditions and 9% to 20% 2-year mortality for heart failure patients with no comorbid conditions.⁶

The clinical course and prognosis for patients with advanced heart failure and preserved ejection fraction (HFpEF) are even more difficult to predict than for those with heart failure and reduced ejection fraction (HFrEF) (see Chapter 27). One community-based study of patients hospitalized with heart failure suggested that the prognosis in patients with chronic heart failure is comparable to that in individuals with reduced and preserved ejection fractions.⁷ However, this has not been a consistent finding inasmuch as another trial of patients with HFpEF found a low rate of heart failure hospitalization or death.⁸ No data specifically provide information on the course for patients with advanced HFpEF. Web-based heart failure prognostic calculators (EFFECT and Seattle)^{9,10} do include patients with preserved ejection fractions and thus can provide a general reference. However, how these calculators perform in the real world for patients with advanced HFpEF is not known.

The course for patients older than 75 years with heart failure is dominated by other conditions. Older persons hospitalized with heart failure are more likely to be readmitted to the hospital for an unrelated diagnosis than for heart failure. Cardiac conditions are more commonly the comorbid illnesses for the young old (65 to 75 years),

whereas unrelated conditions such as dementia and osteoporosis are more common in those older than 76 years.¹¹ In patients 85 years and older hospitalized with heart failure, having three or more non-cardiac-related comorbid conditions increases the likelihood of death within 6 months.¹¹ The combination of dementia and chronic kidney disease is associated with a median survival of less than 1 year for all heart failure patients older than 65 years.

The progressive decline in functional status in the very elderly may be related more to frailty than to the heart failure per se, and both hospitalization and death are often the result of other processes, such as hip fracture or pneumonia in the very old.¹² Frailty, characterized by weakness, fatigue, weight loss, and slow gait speed, is present in a quarter to half of elderly persons with heart failure and is associated with death within 12 years.¹³ Thus although it coexists with heart failure, frailty alone is not a marker for death in the near future. The pathophysiologic features of the sarcopenia (muscle wasting) of frailty and that of heart failure are equivalent, and both may improve with angiotensin-renin-aldosterone blockade.^{7,14}

Cognitive impairment is present in about half of all persons older than 80 years. Vascular dementia secondary to cerebrovascular disease and cognitive impairment secondary to heart failure further compromise the management of very elderly persons with heart failure. Despite the absence of data specific to advanced heart failure, a diagnosis of dementia was present in 22% to 25% of Medicare beneficiaries with heart failure in one database and was associated with a twofold increase in mortality of nonhospitalized elderly heart failure patients.¹¹ Studies of brain function in patients with HFrEF have demonstrated abnormalities in parts of the brain affecting autonomic function, emotion, memory, and executive function.⁵ Management strategies for patients with advanced heart failure thus need to integrate plans to assist in medication compliance, dietary sodium management, assessment of volume status, and titration of diuretics.

COMMUNICATION AND DECISION MAKING IN ADVANCED HEART FAILURE

The mounting options for care of patients with advanced HFrEF in the past decade have increased the complexity of decision making. Many decisions in the care of patients with advanced heart failure rely on both what is medically reasonable for the patient and the patient's values and goals. Discussions that there are choices at a point in care and that these choices depend on what is important to the patient at this stage in life are usually welcomed by patients and their families. Most patients prefer both to feel as good as possible and to live as long as possible while they feel good, but some will prefer a balance between quality and quantity of life. Thus some patients will decide not to undergo a surgical procedure or device implantation or prefer to not spend time in the hospital, even if they will potentially not live as long without these interventions.

Communication with patients who have advanced heart failure includes acknowledging that death is possible. Clinicians should be prepared to answer patients' and family members' questions about prognosis or life expectancy, but it is not necessary to lecture patients about dying or their life expectancy. Ideally, the possibility of death is brought up early in the care of a patient with heart failure. This makes it easier for the patient, family, and physician to cope with dying and sudden death during the course of heart failure.

Physicians sometimes worry that discussions about death may take hope away. A helpful tool is to identify what the patient hopes for and then to also plan for what to do if things do not go as hoped. This "hope for the best but plan for the worst" conversation allows the clinician to set up a dichotomy—hoping along with the patient for the best outcome while simultaneously acknowledging what more realistically may occur, including death.¹⁵

Goals for care may change as the patient's status changes. Many people modify their appraisal of what brings quality to their life and accept more functional limitation over time with a chronic or progressive illness. Thus conditions that a person previously might have deemed unacceptable may become tolerated, and a patient's preferences can change. The goals of care should be readdressed when there is a change in health status, at the time of hospitalization, and at the time of therapy decision points (such as discussions about ICDs, CRT, LVADs, or transplant listing).

Some patients can clearly articulate their goals, whereas others will not have clarified their goals or priorities. Asking what they hope for in the next year or next several months can help identify concrete goals. Reflecting on what has been important to them as they look back at their life is one way to identify values with patients. It is important for the clinician to have an understanding of patients' priorities, clarify an approach to care, and then make recommendations for interventions consistent with that approach.

Patient-centered communication between clinicians and patients can follow a basic framework of "ask-tell-ask":

- Ask patients their current understanding, what they would like to know, and how they want to receive information.
- Tell the information in small digestible amounts in accordance with their preferences.
- Ask what they understood to check their comprehension and ask "What are your questions?"

Asking about patients' understanding permits clinicians to target their discussions so that they meet the specific issues of their patients. When there is a significant need for education, other members of the care team can expend the time needed to provide it before moving on to choosing care.

Some patients prefer not to know details or participate in decision making. In this situation it is appropriate to ask patients to identify someone who will speak for them and make decisions on their behalf. In addition to decisions about interventions or approach to care, all patients with advanced heart failure should identify a durable power of attorney for health care or a surrogate who can make care decisions at a time when they are unable to speak for themselves (**Table 31-1**). Other advance directives, such as a living will, may help in future care decisions. The living will language varies by state law or statute in the United States and generally identifies under what circumstances the person would not want certain life-prolonging interventions. Even though such documents are helpful, they often do not apply specifically to the patient's situation. A durable power of attorney for health care or a health care proxy is thus a more helpful means of ensuring that persons receive care consistent with their preferences.

MEDICAL MANAGEMENT OF ADVANCED HEART FAILURE

Medical management of advanced HFrEF is initially focused on optimizing blockade of the beta-adrenergic and renin-angiotensin-aldosterone systems and managing volume status (**see Chapter 25**). Derangements in these neurohormonal systems are at the basis of symptoms in heart failure (**Fig. 31-1**). In frail elderly heart failure patients or those with advanced heart failure, hypotension and renal dysfunction may limit medication doses, yet in those with HFrEF, small medication doses are warranted to counter the renin-angiotensin-aldosterone and beta-adrenergic disarray and thus help in managing symptoms. No data are of assistance in determining what medication to continue and what to discontinue in advanced heart failure. Most specialists weigh the potential benefits of medications and discontinue those that are unlikely to improve current function or symptoms. An example of a medication to discontinue is a statin, which has an impact on long-term mortality but does not improve symptoms.

Efforts to manage volume status with approaches other than loop diuretics are appropriate. In heart failure, hypoxia is a potential cause of pulmonary hypertension,¹⁶ and nocturnal hypoxia contributes to worsened volume status.¹⁷ Identification and treatment of sleep-disordered breathing with either continuous positive airway pressure (CPAP) or nocturnal oxygen supplementation (**see Chapter 75**) can improve volume status, as well as quality of life and symptoms.¹⁸

Aggressive restriction of oral fluid and sodium intake can improve heart failure status,¹⁹ but patients must be willing to limit oral intake to 1 liter of fluid per day. If tolerated by renal function, the addition of aldosterone blockers may improve volume status. Serum potassium must be carefully monitored in patients receiving aldosterone-blocking agents.

In advanced HFrEF, early studies documented that both symptoms and volume overload improve with blockade of the beta-adrenergic and renin-angiotensin-aldosterone systems, so these medications

might be retained when others are discontinued.¹⁴ Angiotensin receptor blockers are appropriate in patients who do not tolerate angiotensin-converting enzyme (ACE) inhibitors. It is not clear that lower than target doses of beta blockers are beneficial,²⁰ so the beta blocker might be discontinued before the ACE inhibitor. No studies have informed care as patients approach the end of life, but it is possible to evaluate each change in medication and its impact on the individual patient's symptoms and function.

TABLE 31-1 Advance Directives

Durable power of attorney/health care	Designates a health care proxy when individuals are unable to speak for themselves
Living will	Specifies whether to use life-prolonging treatment when "terminally ill"; limited in its application
Five wishes (http://www.agingwithdignity.org/five-wishes.php)	Document designates a health care proxy, treatment desired or not, level of comfort, approach to care, and what you want loved ones to know
Physician (or medical) order for life-sustaining treatment (POLST or MOLST)	Transportable order set for emergency care that designates resuscitation or not, hospitalization or not, artificial hydration, and nutrition or not

When clinicians believe that the prognosis is poor, care that potentially prolongs life is appropriate if it helps manage symptoms or if continuing attempts to prolong life meet a specific goal for the patient or family. In the latter situation, it is appropriate to set goals for care and identify a period after which these goals and the approach to care will be reevaluated. Clinicians should also identify with the patient under what circumstances life-prolonging efforts would be discontinued. In the event of undesired outcomes (stroke, coma) and the patient loses the ability to communicate, clinicians must reassess with the surrogate decision maker and shift the focus of care to allow death.

Symptom Management

Throughout advanced heart failure, pain, dyspnea, fatigue, anxiety, depressed mood, and sleep disturbance are common symptoms. Regardless of the goals for care, these symptoms should be assessed and efforts made to manage them. Management should always include treatment of renin-angiotensin-aldosterone and beta-adrenergic disarray and attempt to optimize heart failure status.

Patient self-report is the most reliable means of assessing symptoms. A tool that might be useful clinically is the Edmonton Symptom Assessment Scale. Although designed to monitor daily symptom severity in cancer patients, this scale has been used in a variety of research in heart failure patients.^{13,21}

Simply asking patients to describe what is most bothersome or what interferes with their life is a reasonable way to target evaluation and management of symptoms. The severity and frequency of a symptom should be queried, as well as what improves and what worsens the symptom.

FIGURE 31-1 Schematic cause of heart failure symptoms. RAAS = renin-angiotensin-aldosterone system; TNF = tumor necrosis factor. (From Goodlin SJ: Palliative care in congestive heart failure. *J Am Coll Cardiol* 54:386, 2009.)

Pain

The prevalence of pain is as high as 84% in patients with advanced heart failure. Some patients have infrequent or mild pain, whereas others have severe or disabling pain.²² Patients frequently have pain at more than one location. A report of pain should be followed by questions about the location and severity of the pain, as well as what makes it better or worse. Because nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with worsened renal function and volume status, patients need specific instructions to not use these over-the-counter agents, and therapeutic alternatives should be discussed. Nonacetylated salicylates (salsalate or Trilisate) may be effective in some patients and do not affect renal function or blood clotting. Salicylate levels should be monitored. Opioid analgesics are safe in alleviating dyspnea²³ and are probably safe for pain. However, opioids such as morphine, which has active renally excreted metabolites, should be avoided for chronic use in heart failure patients (Table 31-2). Although not formally tested in heart failure patients, fentanyl and methadone do not have active metabolites and do not rely on renal excretion. Local treatments such as heat or cold therapy and physical therapy should be considered in a multidisciplinary approach to pain management. Topical capsaicin, topical NSAIDs, and topical salicylates may

TABLE 31-2 Examples of Opioid Medications for Heart Failure Patients

MEDICATION	ADVANTAGES	CAUTIONS	INITIAL DOSE	TITRATION
Morphine	Reduces preload acutely	Renal excretion; metabolites cause delirium, neuroexcitation	2 mg IV or 5-10 mg PO	Not appropriate for long-term use in heart failure
Hydromorphone	Metabolites may have less toxicity	Some metabolites may accumulate	0.05 mg IV or 1 mg PO q3-4 h	Titrate to pain relief
Methadone	Gastrointestinal excretion	Prolongs the QTc at doses of 100 mg/day in some patients	2.5-5 mg PO q8h	Accumulates in tissues after 4-5 days; dose and frequency should be reduced
Fentanyl	Hepatic metabolism; no active metabolites; rapid onset of action buccal form	Approved by the Food and Drug Administration for cancer pain; transdermal doses only for moderate to severe pain	100 µg q2h buccally; 12 or 12.5 mcg/hr patch applied q3day	Buccal doses are rapidly absorbed; transdermal patches are not for opioid-naïve patients and require 8 hours to reach the target dose

also be considered, although no data are available on their use in advanced heart failure.

Dyspnea

Sodium and fluid restriction along with diuretics is essential in maintaining fluid balance and thus decreasing dyspnea from congestion. Dyspnea is present in heart failure patients even when euvolemic and is related to the skeletal myopathy associated with heart failure syndrome.²⁴ Thigh muscle strengthening reduces dyspnea and fatigue in patients with New York Heart Association Functional class II heart failure, possibly by altering the skeletal myopathy, and is appropriate to try in those with advanced heart failure.²⁵ Exercise therapy, including tai chi, can also assist in reducing the sensation of dyspnea in moderate heart failure.

Opioid medications alter chemosensitivity to decrease the perception of dyspnea,²⁶ reduce the responsiveness of the respiratory control center, and decrease anxiety. Opioids increase heart failure patients' exercise tolerance, thereby resulting in a decrease in respiratory effort and a decreased sensation of dyspnea.¹⁴ Although the hemodynamic effects of opioids vary, morphine reduces preload and is appropriate for the acute management of dyspnea. Active morphine metabolites accumulate in patients with renal dysfunction and cause delirium, myoclonus, and other toxicity, so morphine is not appropriate for chronic use in those with advanced heart failure (see Table 31-2).

Nitrates reduce left ventricular end-diastolic pressure and may reduce dyspnea and improve exercise tolerance in patients with and without an ischemic cause of heart failure.

Oxygen supplementation is indicated when the dyspnea is related to arterial hypoxemia, and oxygen or air flowing across the nose and face can stimulate the sensory receptors that modulate the sensation of dyspnea. Nocturnal nasal oxygen supplementation improves exercise capacity and quality of life in patients with HFrEF.²⁷

Noninvasive ventilation through CPAP devices can relieve dyspnea by decreasing the neuromechanical dissociation of the respiratory drive and counterbalancing the inspiratory load on respiratory muscles. CPAP can reverse ventricular remodeling, decrease afterload, improve stroke volume, reduce cardiac sympathetic activity, and improve quality of life.¹⁸

Anxiety and Depression

Anxiety and depression are prevalent in advanced heart failure. All efforts to improve heart failure status may diminish anxiety, as may the patient's and family's understanding and planning of heart failure management. Because norepinephrine and epinephrine levels are markedly elevated in those with sleep apnea and nocturnal hypoxia, identification of sleep-disordered breathing and treatment with either CPAP or nocturnal oxygen supplementation are important to decrease anxiety and depressive symptoms.

Sertraline is safe in moderate heart failure, and may be effective for some patients, although improvement in heart failure status also correlates with improved depression.^{28,29} Paroxetine was effective in decreasing symptoms of depression in a small trial of stable heart failure patients,¹⁷ but no antidepressant has been studied in those

with advanced heart failure. Of note, the selective serotonin reuptake inhibitors cause volume overload and hyponatremia in elderly persons with renal impairment, so serum sodium and volume status must be monitored throughout their use.

Other antidepressants may also be appropriate in patients with advanced heart failure. The tricyclic antidepressants nortriptyline and desipramine are safe but at higher doses cause orthostatic hypotension and can prolong the QT interval. Tricyclic antidepressants require weeks of titration to reach effective doses in most patients. Another option, which is also unstudied in patients with advanced heart failure, is low-dose methylphenidate because this agent can improve fatigue and mood in some patients. It has the advantage of rapid onset of action, so it can be titrated over a period of a few days. If ineffective, it can be abruptly discontinued.

Gastrointestinal Symptoms

Anorexia, weight loss, and protein malnutrition are common features of advanced heart failure and are related to the associated neurohormonal and cytokine abnormalities associated with cachexia in the heart failure syndrome. Intestinal edema, ascites, and hepatic congestion can contribute to early satiety in those with right-sided volume overload. Optimizing volume status and treating sleep apnea and other contributors to pulmonary hypertension may decrease early satiety. Beta blockers and ACE inhibitors counter the cachexia in patients with HFrEF, presumably by reducing neurohormonal and immune dysfunction.²⁷

Fatigue

In patients with heart failure, fatigue is prevalent and associated with a worsening prognosis and increased mortality.³⁰ Fatigue may be due to decreased cardiac output, elevated levels of neurohormones and inflammatory cytokines, deconditioning, sleep impairment, and depression and/or anxiety. Evaluation and treatment of fatigue should be multifaceted. Restriction of fluid and sodium intake results in reduced fatigue, as well as reduced edema and dyspnea. In heart failure patients with anemia, erythropoietin therapy may enhance exercise capacity. Opioids, caffeine, and perhaps other stimulants can improve exertional fatigue.^{26,31} Selective thigh muscle strengthening can improve fatigue in those with chronic heart failure.²⁵

END-OF-LIFE CARE

Care for patients dying of heart failure varies with the site of care and the severity of their organ dysfunction. Death in an acute care hospital may occur suddenly or over a period of days, whereas in outpatient settings the end of life can stretch for many months.

In any setting, clarifying the patient's status and setting goals to manage the end of life are key issues that should be addressed early in the course of heart failure. Reevaluating therapies to focus on symptom management is an important second step.

Therapies that do not enhance symptoms, such as ICDs, can be discontinued in an organized manner to allow natural death. Deactivating an ICD is ethically sound once a decision has been made to allow natural death.

When a patient is acutely ill but ongoing aggressive treatments will not restore meaningful independent function or they are not consistent with the patient's goals and preferences, a decision can be made to discontinue treatments that prolong life. Discontinuation of treatments that are viewed as being critical to sustain life can be more challenging for clinicians. However, decades of medical ethics support the withdrawal of unwanted or futile treatments. A treatment not expected to achieve the desired goals can be considered "futile."

In general, the approach to withdrawal of therapies should follow a consistent approach:

1. Goals for care in the specific setting for this individual patient are set.
2. Treatments inconsistent with goals are identified.
3. The probable course with and without a specific treatment is clarified. Specifically, a range of time in which death might occur with or without the treatment and the nature of the death (sudden versus lingering, any possible suffering) are identified.
4. A specific plan is set, including a scheduled date and time to discontinue a therapy. Generally, monitors for heart rate and rhythm, oxygen saturation, and blood pressure are discontinued.
5. The patient, family, and others are given an opportunity to say goodbye and perform religious or other rituals.
6. The device or treatment is discontinued, with sedation and medications for managing dyspnea or other symptoms being available. A designated clinician stays with the patient or is available to manage any distressing symptoms over time.

Thus in some circumstances, such as discontinuation of a permanent pacemaker in a patient with a previous third-degree heart block or discontinuation of an LVAD in a patient with low output, stopping the treatment will probably result in rapid death. In such situations, opioids should be available to manage dyspnea, and benzodiazepines can be used to manage agitation. In contrast, discontinuation of dialysis might result in death over a week or so, and discontinuation of an ICD or a biventricular pacemaker in a patient who was a non-responder to CRT might not discernibly change the course to death.

Hospice Care

Patients dying in the community are appropriate for hospice care if the physician caring for them (along with the hospice medical director) certifies that life expectancy is approximately 6 months. Proportionally fewer patients with heart failure than with cancer receive hospice care, perhaps in part because of difficulty identifying the last 6 months of life for heart failure patients. Hospice care is variable, with each agency implementing the hospice benefit according to resources, staff availability, knowledge, and skill.³² Heart failure clinicians can manage the care of patients along with hospice staff or work with hospices to set care plans in place for heart failure patients.²⁴

Coping with Patients' Deaths

Clinicians caring for patients with a life-limiting illness witness death repeatedly. Frequently death is expected, which allows the clinician to prepare with the patient and family for death and say goodbye to the patient, but death also comes unexpectedly despite every effort to fend it off. In any form, death is sad and affects medical providers, as well as the patient's loved ones. Physicians and other clinicians must develop strategies to cope with patients' deaths.

Acknowledging to patients and families that death is possible early in the course of care also prepares the clinician and makes it easier to cope with death even when it comes as a surprise. Honest appraisal of the prognosis to oneself, recognizing the uncertainty of any one patient's course or length of life, and being able to communicate these issues honestly as needed to patients and their families are essential in managing heart failure as a physician or nurse. Physicians and other clinicians caring for heart failure patients build relationships with them and their significant others. Particularly when the patient is ill, the relationship is very intense. Death ends the relationship, and often when the relationship was founded on trying to keep the person alive, death calls our inadequacy and limitations to our attention. Coping with the emotions brought up by the many implications of death requires us to identify and accept them.

Rituals following death are a way to name and accept emotions. Some physicians attend memorials or other services for patients, but more often death and the remembrances occur during a busy day. Writing to or calling the family to express condolences is one way to close the relationship with the patient and acknowledge one's own grief. A note or a call should extend condolences for the family's loss, communicate that the clinician valued his or her role in providing care, and identify the positive aspects of the patient's life and the family's effort.

Ultimately, it is also important to find sources of support for the clinician's own sadness and grief. For many, simply acknowledging the sadness to friends and colleagues helps. Care of heart failure obliges us to witness sadness during the course of illness and at the end of life. Death is a reality of heart failure care, and clinicians must support each other around death, just as diligently as we work together to prolong life.

Cardiac arrhythmias encompass a large and heterogeneous group of electrical abnormalities of the heart, with or without underlying structural heart disease. Cardiac arrhythmias can be innocuous, can predispose to the development of potentially lethal stroke or embolism, or can be an emergency, life-threatening condition that may result in sudden cardiac death (SCD), one of the most common causes of death in the developed countries. In the United States, for example, an estimated 300,000 to 400,000 individuals die suddenly each year, with the vast majority involving the elderly; 80% are caused by ventricular fibrillation in the context of ischemic heart disease. In comparison, SCD in the young is relatively uncommon, with an incidence between 1.3 and 8.5 per 100,000 patient-years.¹ However, tragically, thousands of otherwise healthy individuals younger than 40 years die suddenly each year without warning. Most SCD in the young can be attributed to structural cardiovascular anomalies identifiable at autopsy, but in as many as 30% to 50% of such individuals, sudden death remains unexplained following a complete autopsy and medicolegal investigation (see Chapter 39).

Potentially lethal and inheritable arrhythmia syndromes included under the umbrella of “cardiac channelopathies,” such as congenital long-QT syndrome (LQTS), Brugada syndrome (BrS), catecholaminergic polymorphic ventricular tachycardia (CPVT), and related disorders, involve electrical disturbances with the propensity to produce fatal arrhythmias in the setting of a structurally normal heart. These often unassuming electrical abnormalities have the capacity to cause a potentially lethal arrhythmia to develop in the heart of an unsuspecting, otherwise healthy individual and lead to sudden and early demise.¹ In fact, it is now recognized that almost a third of autopsy-negative sudden unexplained deaths (SUDs) in the young² and approximately 10% of cases of sudden infant death syndrome (SIDS) stem from these genetically inherited cardiac channelopathies.^{3,4}

Through molecular advances in the field of cardiovascular genetics, the underlying genetic bases responsible for many inherited cardiac arrhythmia syndromes have come to light, and the underlying genetic substrates responsible for other such syndromes are on the cusp of discovery. Over the past decade, a particular set of themes, including extreme genetic heterogeneity, reduced or incomplete penetrance, and variable expressivity, has proved to be commonplace among the cardiac channelopathies. However, for some disorders, important genotype-phenotype correlates have been

recognized and have provided diagnostic, prognostic, and therapeutic impact. The clinical description, genetic basis, and genotype-phenotype correlates associated with these inherited arrhythmia syndromes are discussed in this chapter.

THE QT-OPATHIES

Long-QT Syndrome

Clinical Description and Manifestations of Long-QT Syndrome

Congenital LQTS comprises a distinct group of cardiac channelopathies characterized by delayed repolarization of the myocardium, QT prolongation (QTc >480 msec as the 50th percentile in genetically confirmed LQTS cohorts), and increased risk for syncope, seizures, and SCD in the setting of a structurally normal heart and otherwise healthy individual. The incidence of LQTS may exceed 1 in 2500 persons.⁵ Individuals with LQTS may or may not manifest QT prolongation on a resting 12-lead surface electrocardiogram (ECG). This repolarization abnormality is almost always without consequence; however, triggers such as exertion, swimming, emotion, auditory stimuli (e.g., alarm clock), and the postpartum period can rarely cause the heart to become electrically unstable and result in the development of the potentially life-threatening and sometimes lethal arrhythmia of torsades de pointes (TdP) (see Chapter 37). Although the cardiac rhythm most often returns to normal spontaneously, with only a transient episode of syncope, 5% of individuals with untreated and unsuspected LQTS succumb to a fatal arrhythmia as their sentinel event. However, it is estimated that nearly half of the individuals experiencing SCD stemming from this very treatable arrhythmogenic disorder may have previously exhibited warning signs (i.e., exertional syncope, family history of premature sudden death) that went unrecognized.² LQTS may explain approximately 20% of autopsy-negative SUDs in the young and 10% of cases of SIDS.^{2,3}

Genetic Basis for Long-QT Syndrome. LQTS is a genetically heterogeneous disorder largely inherited in an autosomal dominant pattern; it was previously known as Romano-Ward syndrome. Rarely, LQTS is inherited as a recessive trait first described by Jervell and Lange-Nielsen and is characterized by a severe cardiac phenotype and sensorineural hearing loss. Spontaneous/sporadic germline mutations

can account for nearly 5% to 10% of cases of LQTS. To date, hundreds of mutations have been identified in 10 LQTS susceptibility genes responsible for a nonsyndromic “classic” LQTS phenotype. In addition, two extremely rare, multisystem disorders associated with marked QT prolongation: Timothy syndrome (TS), formerly annotated as LQT8, and prolonged QU intervals (Anderson-Tawil syndrome [ATS], formerly annotated as LQT7), and a third disorder, LQT4, which is better classified as ankyrin-B syndrome, have also been described.

Approximately 75% of patients with a clinically robust diagnosis of LQTS host either loss-of-function or gain-of-function mutations in one

of three major LQTS genes (Table 32-1)—the *KCNQ1*-encoded I_{Ks} ($K_v7.1$) potassium channel (LQT1, ≈35%; loss of function), the *KCNH2*-encoded I_{Kr} ($K_v11.1$) potassium channel (LQT2, ≈30%; loss of function), and the *SCN5A*-encoded I_{Na} ($Na_v1.5$) sodium channel (LQT3, ≈10%, gain of function)—that are responsible for orchestration of the cardiac action potential^{6,7} (Fig. 32-1). Approximately 5% to 10% of patients have multiple mutations in these genes, and those with multiple LQTS mutations are affected at a younger age and exhibit greater expressivity⁶ (see Chapter 8). The most recent discovery was reported in 2012 by Boczek and colleagues following whole exome sequencing,

TABLE 32-1 Summary of Heritable Arrhythmia Syndrome Susceptibility Genes

GENE	LOCUS	PROTEIN	GENE	LOCUS	PROTEIN
Long-QT Syndrome			Brugada Syndrome		
Major LQTS Genes			<i>SCN5A</i> (BrS1)	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
<i>KCNQ1</i> (LQT1)	11p15.5	I_{Ks} potassium channel alpha subunit (KVLQT1, $K_v7.1$)	Minor BrS Genes (listed alphabetically)		
<i>KCNH2</i> (LQT2)	7q35-36	I_{Kr} potassium channel alpha subunit (HERG, $K_v11.1$)	<i>GPD1L</i>	3p22.3	Glycerol-3-phosphate dehydrogenase 1-like
<i>SCN5A</i> (LQT3)	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)	<i>CACNA1C</i>	12p13.3	Voltage gated L-type calcium channel ($Ca_v1.2$)
Minor LQTS Genes (Listed Alphabetically)			<i>CACNA2D1</i>	7q21-q22	Voltage gated L-type calcium channel 2 delta 1 subunit
<i>AKAP9</i>	7q21-q22	Yotiao	<i>CACNB2</i>	10p12	Voltage gated L-type calcium channel beta 2 subunit
<i>CACNA1C</i>	12p13.3	Voltage gated L-type calcium channel ($Ca_v1.2$)	<i>DLG1</i>	3q29	Synapse-associated protein 97
<i>CAV3</i>	3p25	Caveolin-3	<i>KCND3</i>	1p13.2	Voltage-gated potassium channel (I_{to}) subunit $K_v4.3$
<i>KCNE1</i>	21q22.1	Potassium channel beta subunit (MinK)	<i>KCNE3</i>	11q13.4	Potassium channel beta subunit 3 (MiRP2)
<i>KCNE2</i>	21q22.1	Potassium channel beta subunit (MiRP1)	<i>KCNE5</i>	Xq22.3	Potassium channel beta subunit 5
<i>KCNJ5</i>	11q24.3	Kir3.4 subunit of I_{KACH} channel	<i>KCNJ8</i>	12p12.1	Inward rectifier K^+ channel Kir6.1
<i>SCN4B</i>	11q23.3	Sodium channel beta 4 subunit	<i>HCN4</i>	15q24.1	Hyperpolarization-activated cyclic nucleotide-gated channel 4
<i>SNTA1</i>	20q11.2	Syntrophin-alpha 1	<i>MOG1</i>	17p13.1	RAN guanine nucleotide release factor 1
Andersen-Tawil Syndrome			<i>SCN1B</i>	19q13	Sodium channel beta 1
<i>KCNJ2</i> (ATS1)	17q23	I_{K1} potassium channel (Kir2.1)	<i>SCN3B</i>	11q24.1	Sodium channel beta 3
Timothy Syndrome			<i>SLMAP</i>	3p14.3	Sarcolemma associated protein
<i>CACNA1C</i>	12p13.3	Voltage gated L-type calcium channel ($Ca_v1.2$)	Early Repolarization Syndrome		
Short-QT Syndrome			<i>CACNA1C</i>	12p13.3	Voltage gated L-type calcium channel ($Ca_v1.2$)
<i>KCNH2</i> (SQT1)	7q35-36	I_{Kr} potassium channel alpha subunit (HERG, $K_v11.1$)	<i>CACNA2D1</i>	7q21-q22	Voltage gated L-type calcium channel 2 delta 1 subunit
<i>KCNQ1</i> (SQT2)	11p15.5	I_{Ks} potassium channel alpha subunit (KVLQT1, $K_v7.1$)	<i>CACNB2</i>	10p12	Voltage gated L-type calcium channel beta 2 subunit
<i>KCNJ2</i> (SQT3)	17q23	I_{K1} potassium channel (Kir2.1)	<i>KCNJ8</i>	12p12.1	Inward rectifier K^+ channel Kir6.1
<i>CACNA1C</i> (SQT4)	12p13.3	Voltage gated L-type calcium channel ($Ca_v1.2$)	Progressive Cardiac Conduction Disease		
<i>CACNB2</i> (SQT5)	10p12	Voltage gated L-type calcium channel beta 2 subunit	<i>SCN5A</i>	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
<i>CACN2D1</i> (SQT6)	7q21-q22	Voltage gated L-type calcium channel 2 delta 1 subunit	<i>TRPM4</i>	19q13.33	Transient receptor potential cation channel, subfamily M, member 4
Catecholaminergic Polymorphic Ventricular Tachycardia			Sick Sinus Syndrome		
<i>RYR2</i> (CPVT1)	1q42.1-q43	Ryanodine receptor 2	<i>ANKB</i>	4q25-q27	Ankyrin-B
<i>CASQ2</i> (CPVT2)	1p13.3	Calsequestrin 2	<i>HCN4</i>	15q24-q25	Hyperpolarization-activated cyclic nucleotide-gated channel 4
<i>KCNJ2</i> (CPVT3)	17q23	I_{K1} potassium channel (Kir2.1)	<i>SCN5A</i>	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
<i>CALM1</i>	14q32.11	Calmodulin 1			
<i>TRDN</i>	6q22.31	Triadin			

genomic triangulation, and a systems biology approach to identify a novel genetic substrate (P857R-CACNA1C) for a large 15-member (8 affected) multigenerational pedigree with autosomal dominant “classic” LQTS.⁸ Functional characterization of the mutation via a whole-cell patch clamp technique revealed a gain-of-function mutation in peak $I_{Ca,L}$ consistent with prolongation of the cardiac action

FIGURE 32-1 Cardiac action potential disorders. Illustrated are the key ion currents (white circles) along the ventricular cardiocyte's action potential that are associated with potentially lethal cardiac arrhythmia disorders. Disorders resulting in gain-of-function mutations are shown in green rectangles and those with loss-of-function mutations are shown in blue rectangles. For example, gain-of-function mutations in the *SCN5A*-encoding cardiac sodium channel responsible for I_{Na} lead to LQTS, and loss-of-function *SCN5A* mutations result in BrS, cardiac conduction disorder (CCD), and sick sinus syndrome (SSS). AF = atrial fibrillation.

FIGURE 32-2 Probabilistic nature of LQTS genetic testing. Depicted are the three major ion channels involved in LQTS, with areas of probability of pathogenicity shown for mutations localizing to these respective areas. Even though “radical” mutations have greater than a 90% probability of being a true pathogenic mutation, the level of probability for missense mutations varies depending on their location for each channel protein. Missense mutations residing in red-shaded areas have a high probability (>80%) of being pathogenic, those in blue are possibly (51% to 80%) pathogenic, and those in yellow-shaded areas truly represent variants of uncertain significance (VUS, ≤50% probability) clinically. cNBD = cyclic nucleotide binding domain; PAC = PAS-associated C terminal; PAS = per (period circadian protein) arnt (aryl hydrocarbon receptor nuclear translocator protein) sim (single-minded protein); SAD = subunit assembly domain.

potential and the clinical phenotype of LQTS. Their subsequent mutational analysis of 102 unrelated patients with robust clinical evidence of LQTS has indicated that 3% to 5% of genetically elusive cases of LQTS may be attributed to *CACNA1C* mutations, thus making *CACNA1C* potentially the fifth most common genetic substrate for nonsyndromic LQTS. The majority of the mutations identified reside in the *CACNA1C*-encoded critical PEST domain of the L-type calcium channel (LTCC), which signals for rapid protein degradation. These mutations presumably result in a biogenic increase in LTCCs at the cell surface membrane.

The remaining seven minor LQTS susceptibility genes encode for either cardiac ion channels or key cardiac channel interacting proteins (“ChIPs”) that generally regulate the native ion channel current and collectively explain perhaps 5% of cases of LQTS. The vast majority of LQTS susceptibility mutations consist of single nucleotide substitutions or small insertions/deletions resulting in nonsynonymous missense (amino acid substitution for another amino acid), nonsense (amino acid substitution for a termination codon), or splice site alterations (resulting in exon skipping or intron inclusion) or frameshift mutations (altered normal amino acid coding resulting in early termination).^{6,7,9} Recently, a few large gene rearrangements involving hundreds to thousands of nucleotides resulting in single or multiple deletions/duplications of whole exons have been described.^{10,11} Importantly, quintessential mutational “hot spots” are not present within these genes, with the vast majority of unrelated families having their own unique “private” mutation. In 2013 it is important to note that nearly 20% of clinically definite cases of LQTS remain genetically elusive.

In contrast to the rare, pathogenic LQTS-associated channel mutations present in less than 0.04% (1/2500) of persons and in 75% of clinically robust LQTS cases, comprehensive genetic testing for *KCNQ1*, *KCNH2*, and *SCN5A* in more than 1300 ostensibly healthy volunteers has revealed that approximately 4% of white individuals and up to 8% of nonwhite individuals host rare nonsynonymous genetic variants (<0.5% allelic frequency) of these specific cardiac channel genes.¹² In fact, a total of 79 distinct channel variants were detected in these healthy subjects, including 14 variants in *KCNQ1*, 28 in *KCNH2* and 37 in *SCN5A*.¹² This has enabled a case-control mutational analysis of the

properties and localization of case-associated mutations relative to the compendium of presumably innocuous variants.¹² The probabilistic rather than the binary nature of genetic testing is depicted in Figure 32-2, which shows that rare mutations other than missense mutations (approximately 20% of the LQTS spectrum of mutations) are high-probability LQTS-associated mutations whereas the probability of pathogenicity for the most common mutation type, missense mutations (i.e., single amino acid substitutions), is strongly location dependent. For example, missense mutations localizing to the transmembrane-spanning/pore domains of the LQT1- and LQT2-associated potassium channels are high-probability disease mutations, whereas a similarly rare missense mutation that localizes to the domain I-II linker of the Na_v1.5 sodium channel is indeterminate, a variant of uncertain significance (VUS). Without cosegregation or functional data, such a mutation has a point estimate for probability of pathogenicity of less than 50%.

In addition to this background frequency (4% to 8%) of rare variants in health, 15 unique common polymorphisms (allelic frequency >0.5%) have been identified in the four potassium channel subunit genes (*KCNQ1*, *KCNH2*, *KCNE1*, and *KCNE2*), and 8 common polymorphisms have been identified in the sodium channel gene (*SCN5A*). Many of these rare and common polymorphisms represent innocent bystanders; however, a layer of complexity is added to the genetics of these channelopathies, and management of patients with otherwise apparently innocuous variants can modify disease. For example, the most common sodium channel variant, H558R, which has a minor allelic frequency of approximately

29% in blacks, 23% in Hispanics, 20% in whites, and 9% in Asians, can provide a modifying effect on the disease state through “intragenic complementation” (the interaction of two mutations within the same gene that produces a novel functional effect) of other *SCN5A* mutations.¹³ In fact, several studies have indicated that some of these common polymorphisms may be informative clinically and relevant to the identification of those at risk for cardiac arrhythmias, particularly in the setting of TdP-inducing drugs or other environmental factors, as discussed later in this chapter.

Genotype-Phenotype Correlates in Long-QT Syndrome

The emergence of specific genotype/phenotype associations in LQTS suggest relatively gene-specific triggers, ECG patterns, and response to therapy (Fig. 32-3). Swimming- and exertion-induced cardiac events are strongly associated with mutations in *KCNQ1* (LQT1), whereas auditory triggers and events occurring during the postpartum period most often occur in patients with LQT2. Whereas exertion- or emotional stress-induced events are most common in LQT1, events occurring during periods of sleep or rest are most common in LQT3. In a study population of 721 LQT1 and 634 LQT2 genetically confirmed patients from the U.S. portion of the international LQTS registry, a multivariate analysis was used to assess the independent contribution of clinical and mutation-specific factors to the occurrence of a first triggered event associated with exercise, arousal, or sleep/rest.^{14,15} Among the 221 symptomatic LQT1 patients, the first cardiac event was most often associated with exercise (55%), followed by sleep/rest (21%), arousal (14%), and nonspecific (10%) triggers; in contrast, the 204 symptomatic LQT2 patients most often had their first event associated with either arousal triggers (44%) or nonexercise/nonarousal triggers (43%), and only 13% of the symptomatic LQT2 patients had an exercise-triggered first event. In addition, males younger than 13 years with LQT1 had a nearly 3-fold increase in risk for exercise-triggered events, whereas females 13 years or older with LQT1 had a 3.5-fold increase in risk for sleep/rest nonarousal events. For LQT2 patients, the rate of arousal-triggered events was similar between boys and girls, but the rate of arousal-triggered events was significantly higher in women than in men (26% versus 6% at 40 years of age) after the onset of adolescence. Characteristic gene-suggestive ECG patterns have been described previously. LQT1 is associated with a broad-based T wave, LQT2 with a low-amplitude notched or biphasic T wave, and LQT3 with a long isoelectric segment followed by a narrow-based T wave.

However, exceptions to these relatively gene-specific T wave patterns exist, and thus due caution must be exercised when making a pre-genetic test prediction of the particular LQTS subtype involved because the most common clinical mimicker of an LQT3-appearing ECG is seen in patients with LQT1. This is key to keep in mind because importantly, the underlying genetic basis heavily influences the response to standard LQTS pharmacotherapy (beta blockers), with beta blockers being extremely protective in LQT1 patients and moderately protective in patients with LQT2 and LQT3.¹⁶ Additionally, targeting the pathologic LQT3-associated late sodium current with agents such as mexiletine, flecainide, or ranolazine may represent a gene-specific therapeutic option for LQT3.^{17,18} Attenuation in repolarization with clinically apparent shortening of the QTc has been demonstrated with such a strategy, although no evidence-based survival benefit has been shown thus far.¹⁸ Realistically, however, at least a

FIGURE 32-3 Genotype-phenotype correlations in LQTS. Seventy-five percent of cases of clinically strong LQTS are due to mutations in three genes (*KCNQ1*, 35%; *KCNH2*, 30%; and *SCN5A*, 10%) encoding for ion channels that are critically responsible for orchestration of the cardiac action potential. Genotype-phenotype correlations have been observed, including swimming/exertion/emotion and LQT1, auditory triggers/postpartum period and LQT2, and sleep/rest and LQT3.

30-year study may be needed for the latter. Even though the generalization that beta blocker efficacy depends on the genotype has been well accepted, the effectiveness of beta blocker therapy may be largely trigger-specific rather than dependent on genotype. In patients with either LQT1 or LQT2, beta blockade was associated with a pronounced 71% (LQT2 patients) to 78% (LQT1 patients) reduction in the risk for exercise-triggered cardiac events but had no statistically significant effect on the apparent risk for arousal- or sleep/rest-triggered events.^{4,15} However, it should be noted that many symptomatic LQT1 and LQT2 patients experience a subsequent cardiac event associated with a different trigger. For example, an LQT2 patient first experiencing an arousal event or one during sleep may subsequently have an exercise-triggered event. Therefore, beta blocker therapy still remains first-line therapy even for patients experiencing a non-exercise-associated first event.

In addition, intragenotype risk stratification has been completed for the two most common subtypes of LQTS based on mutation type, mutation location, and cellular function.^{19,22} Patients with LQT1 secondary to K_v7.1 missense mutations localizing to the transmembrane-spanning domains clinically have a twofold greater risk for an LQT1-triggered cardiac event than do LQT1 patients with mutations localizing to the C-terminal region. In addition, missense mutations localizing to the so-called cytoplasmic loops (C-loops) within the transmembrane-spanning domains, an area of the protein involved in the regulation of adrenergic channels, are associated with the highest rate of both exercise- and arousal-triggered events but not with an increase rate of sleep/rest-associated events.¹⁵ C-loop K_v7.1 missense mutations were consistently associated with greater than a sixfold increase in risk for exercise-triggered events in comparison to nonmissense mutations and an almost threefold increase in comparison to N- and C-terminal missense mutations.¹⁵

Patients with mutations resulting in a greater degree of K_v7.1 loss of function at the cellular in vitro level (i.e., dominant negative) have a twofold greater clinical risk than that of patients with mutations that damage the biology of the K_v7.1 channel less severely (haploinsufficiency). Adding to the traditional clinical risk factors, molecular location and cellular function are independent risk factors used in the

evaluation of patients with LQTS.²⁰ Akin to molecular risk stratification in LQT1, patients with LQT2 secondary to $K_v11.1$ pore region mutations have a longer QTc and more severe clinical manifestation of the disorder and experience significantly more arrhythmia-related cardiac events occurring at a younger age than do LQT2 patients with non-pore-related mutations in $K_v11.1$.²³ Similarly, in a Japanese cohort of LQT2 patients, those with pore mutations had a longer QTc, and although not significant among probands, nonprobands with pore mutations experienced their first cardiac event at an earlier age than did those with a non-pore-related mutation.²¹ Most recently, additional information has been gleaned suggesting that LQT2 patients with mutations involving the transmembrane pore region had the greatest risk for cardiac events, those with frameshift/nonsense mutations in any region had intermediate risk, and those with missense mutations in the C-terminus had the lowest risk for cardiac events.²² Interestingly, LQT2 patients with mutations in the pore loop region of the $K_v11.1$ channel have a greater than twofold increased risk for arousal-triggered events, and LQT2 patients with non-pore loop transmembrane region mutations have an almost sevenfold increase in the risk for exercise-triggered cardiac events over patients with N-terminal/C-terminal (non-PAS domain) mutations.²⁴

Incomplete penetrance and variable expressivity are the clinical hallmark features of LQTS, and it has long been thought that co-inheritance of a true disease-causing mutation and either a common or rare channel genetic variant may determine the expressed severity of the disorder. For example, coexistence of the common K897T-KCNH2 polymorphism and the A1116V-KCNH2 mutation (on opposite alleles) led to a more severe clinical course in a single Italian LQTS family. The A1116V mutation by itself produced a subclinical phenotype of mild QT prolongation and an asymptomatic course, whereas the proband hosting both variants had clinically overt

disease consisting of diagnostic QT prolongation, presyncope episodes, and cardiac arrest.²⁵ Besides cardiac ion channels, single nucleotide polymorphisms (SNPs) of non-ion channel genes such as *NOS1AP* (the gene encoding the nitric oxide synthase 1 adapter protein), *ADRA2C* (alpha_{2C}-adrenergic receptor), and *ADRB1* (beta₁-adrenergic receptor) may modify disease severity in LQTS.²⁶⁻²⁹

In 2012, Amin and colleagues provided compelling evidence for a strong disease-modifying effect of a 3' untranslated region (3'UTR), *KCNQ1* allele-specific haplotype in LQT1 mutation-positive pedigrees; the magnitude of the effect on the QTc and symptomatology goes well beyond any other currently described genetic modifiers.³⁰ The *KCNQ1* gene encodes for a single $K_v7.1$ ion channel alpha subunit. Following *KCNQ1* gene expression and post-translational modifications, four alpha subunits are assembled to create a pore-forming $K_v7.1$ tetrameric channel. Therefore, if a patient had a heterozygous *KCNQ1* mutation (i.e., one normal *KCNQ1* gene allele and one mutant allele), one would expect that if both the normal and mutant gene alleles were expressed in equal amounts, $\frac{1}{6}$ of the channels would be normal homomeric tetramers and $\frac{1}{6}$ would be mutant homomeric tetramers. The remaining channels would be hybrids containing both normal and mutant alpha subunits. One would predict that if the normal *KCNQ1* gene allele expression was somehow suppressed, there would be relatively more *KCNQ1* mutant alpha subunits translated and ultimately assembled to provide more dysfunctional *KCNQ1* channels and thus lead to a more severe manifestation of the disorder (Fig. 32-4). Simply put, far more bad (mutant) channels than good (healthy) channels would be created. The opposite would be true if the mutation containing the *KCNQ1* allele were suppressed.

Most genes have a 3'UTR that produces an mRNA transcript that contains regions of cis-regulatory binding sites for small noncoding

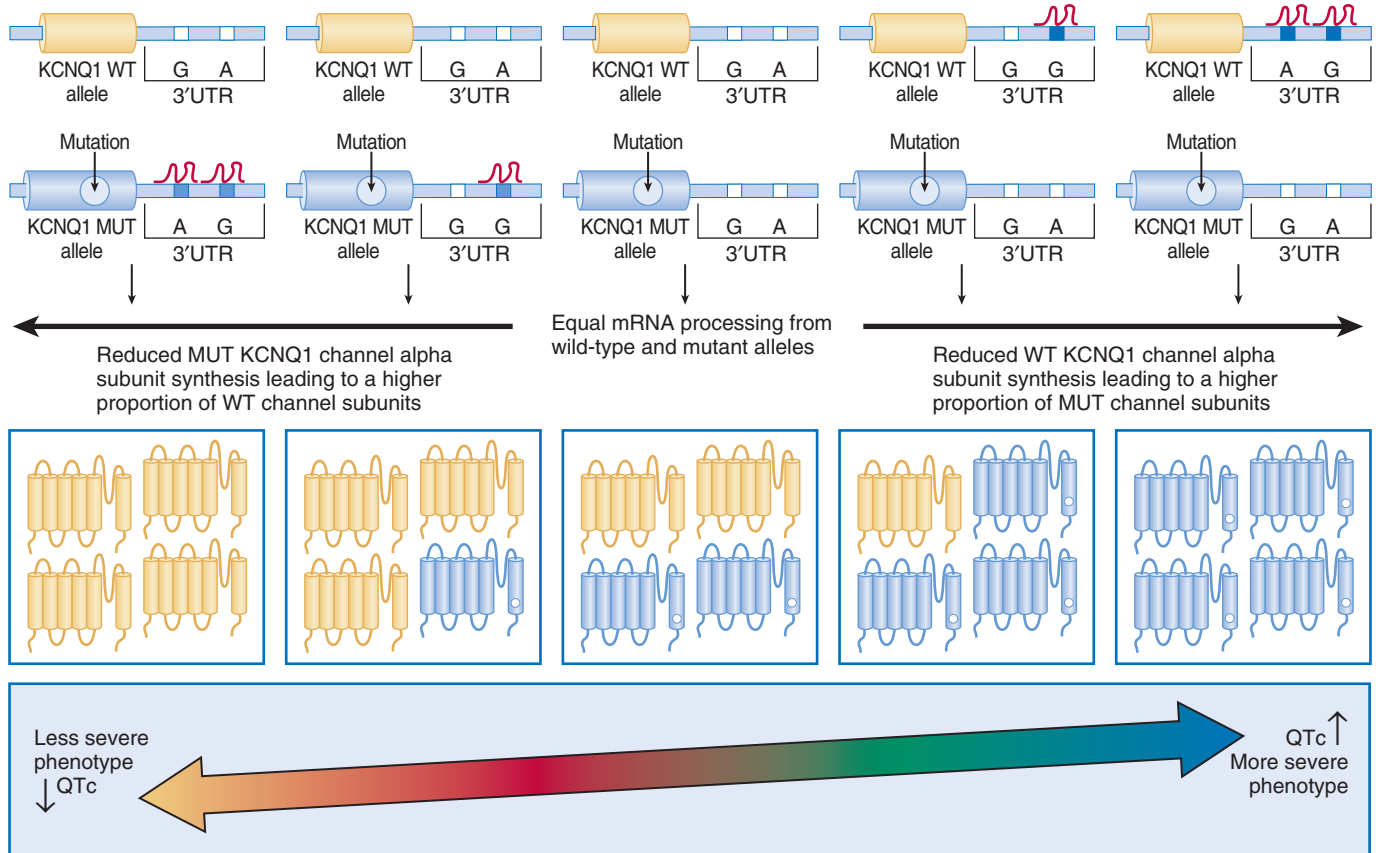

FIGURE 32-4 Hypothesized allele-specific mechanism of LQT1 disease modification by *KCNQ1* 3'UTR SNPs. Illustrated is the proposed microRNA-mediated allele-specific *KCNQ1* gene transcript–"suppressing" mechanism by the existence of naturally occurring SNPs within the *KCNQ1* 3'UTR whereby the presence of their minor alleles (A, G; blue squares) creates a "suppressive" haplotype by creating new microRNA (shown in red) binding sites that suppress expression of the *KCNQ1* gene allele in which they reside, thus altering the stoichiometric assembly of wild-type (i.e., normal, shown in yellow; WT) and mutant (shown in blue; MUT) $K_v7.1$ alpha subunits. (Modified from Amin AS, Giudicessi JR, Tijssen AJ, et al: Variants in the 3' untranslated region of the *KCNQ1*-encoded $K_v7.1$ potassium channel modify disease severity in patients with type 1 long QT syndrome in an allele-specific manner. *Eur Heart J* 33:714, 2012.)

microRNA (miRNA) molecules that bind to the transcript and ultimately inhibit that gene's expression. Naturally occurring genetic variation within these 3'UTRs (miR-SNPs) can either abolish existing or create new miRNA binding sites. Amin and colleagues identified three naturally occurring SNPs (rs2519184, rs8234, and rs10798) within the *KCNQ1* 3'UTR whereby the presence of their minor alleles (A, G, G) generates a "suppressive" haplotype by creating new miRNA binding sites that suppress expression of the *KCNQ1* gene allele in which they reside.³⁰ In a cohort of 168 *KCNQ1* (LQT1) mutation-positive individuals from 41 families, Amin and colleagues showed that inheritance of the "suppressive" haplotype residing on the normal "healthy" allele produced a more severe LQT1 phenotype with regard to QTc and symptomatology than did inheritance of the "suppressive" haplotype residing on the same allele as the *KCNQ1* mutation (shorter QTc and fewer symptoms).³⁰ This intriguing discovery may not only explain a significant component of the reduced penetrance and variable expressivity that is a common feature of arrhythmia syndromes but may also represent a paradigm shift in our thinking about disease-modifying genetic drivers of mendelian disorders because one of the most important genetic determinants of disease severity in LQT1 appears to be the 3'UTR *KCNQ1* haplotype on the allele inherited from the unaffected "non-LQTS" parent.

In 2011, the Heart Rhythm Society (HRS) and the European Heart Rhythm Association (EHRA) released the first HRS/EHRA-sponsored guidelines for clinical genetic testing for LQTS and the other channelopathies and can be reviewed therein.³¹

Andersen-Tawil Syndrome

Clinical Description and Manifestations of Andersen-Tawil Syndrome

ATS, first described in 1971 in a case report by Andersen and later described by Tawil in 1994, is now recognized as a rare, multisystem disorder characterized by a triad of clinical findings, including periodic paralysis, dysmorphic features, and ventricular arrhythmias.³² ATS is a heterogeneous disorder that is either sporadically or autosomal dominantly derived and has a high degree of variable phenotypic expression and incomplete penetrance, with as many as 20% of mutation-positive subjects being nonpenetrant.³² The mean age at the onset of periodic paralysis has been reported to be 5 years (ranging from 8 months to 15 years) and slightly older, 13 years (range, ≈4 to 25 years), for cardiac symptoms.³²

ECG abnormalities in ATS may include pronounced QTU prolongation, prominent U waves, and ventricular ectopy, including polymorphic ventricular tachycardia (VT), bigeminy, and bidirectional VT. Even though ventricular ectopy is common and ectopic density can be high in some patients, most patients with ATS are asymptomatic and SCD is extremely rare.³³ ATS1 was initially proposed as type 7 LQTS (LQT7) because of the observation of extreme prolongation of the QT interval; however, these measurements included the prominent U wave.³⁴ Accordingly, this complex clinical disorder, manifested at times with only a modest prolongation of the QT interval, is probably best considered as its own clinical entity and be referred to as ATS1 rather than as part of the LQTS regime. However, given the potential for false interpretation of the QT interval because of the prominent U wave and the probability of phenotypic expression of only cardiac-derived symptomatology (i.e., syncope, palpitations, ventricular rhythm disturbances), a considerable number of patients with ATS are conceivably misdiagnosed as having classic LQTS. Similarly, the presence of bidirectional VT, an accepted hallmark of CPVT (see later), often leads to ATS being misdiagnosed as the potentially lethal disorder CPVT. Correctly distinguishing between ATS and CPVT is critical because the treatment strategies are different.³⁵

Genetic Basis for Andersen-Tawil Syndrome. To date, almost 40 unique mutations in *KCNJ2* have been described as being causative of ATS1. Mutations in *KCNJ2* account for approximately two thirds of cases of ATS, whereas the molecular basis of the residual third of ATS cases remains genetically and mechanistically elusive. However, the prevalence of *KCNJ2* mutations may be as high as 75% in patients with at least two ATS phenotypic features (i.e., typical ATS).³⁶

Localized to chromosome 17q23, *KCNJ2* encodes for Kir2.1, a small potassium channel alpha subunit expressed in brain, skeletal muscle, and heart that is critically responsible for the inward-rectifying cardiac I_{K1} current (see Table 32-1 and Fig. 32-1). In the heart, I_{K1} plays an important role in setting the heart's resting membrane potential, buffering extracellular potassium, and modulating the action potential waveform. Most *KCNJ2* mutations described in ATS are missense mutations that cause a loss of function of I_{K1} , either through a dominant negative effect on Kir2.1 subunit assembly or through haploinsufficiency as a result of protein trafficking defects.³⁷

Genotype-Phenotype Correlates in Andersen-Tawil Syndrome

Genotype-specific ECG features of ATS are beginning to emerge. In a study by Zhang and colleagues in which T-U ECG morphology was examined, 91% of *KCNJ2* mutation-positive ATS1 patients had characteristic T-U wave patterns (including a prolonged terminal T wave downslope, a wide T-U junction, and biphasic and enlarged U waves) as opposed to none of the 61 unaffected family members or 29 genotype-negative ATS patients.³⁴ In a 2012 study by Kimura and associates, 88% of their *KCNJ2* mutation-positive ATS patients had an abnormal U wave.³⁶ Additionally, although the U wave is markedly abnormal in ATS1, it is typically normal in LQTS. Consequently, this *KCNJ2* gene-specific ECG feature of T-U morphology can be very useful in differentiating ATS1 patients from *KCNJ2* mutation-negative ATS and LQT1 to LQT3 patients and may facilitate a cost-effective approach to genetic testing of the appropriate disorder.³⁴ Interestingly, the topologic location of *KCNJ2* mutations may influence the phenotypic expression of ATS features. The vast majority (≈90%) of *KCNJ2* mutations reside in either the N- or C-terminus of this two-transmembrane single-pore channel. C-terminal mutations appear to be more often associated with typical ATS (more than two ATS features), dysmorphism, and periodic paralysis, whereas N-terminal mutations were more often observed in atypical ATS cases (only one ATS feature, predominately a cardiac phenotype only).³⁶

Timothy Syndrome

Clinical Description and Manifestations of Timothy Syndrome

TS is an extremely rare (<30 patients described worldwide) multisystem, highly lethal arrhythmia disorder associated with both cardiac and extracardiac abnormalities. The typical cardiac manifestations of TS include fetal bradycardia and extreme prolongation of the QT interval (QTc >500 msec), often with macroscopic T wave alternans and a 2:1 atrioventricular (AV) block at birth.³⁸ These abnormalities frequently coincide with congenital heart defects or cardiomyopathies. The extracardiac abnormalities often consist of simple syndactyly (webbing of the toes and fingers), dysmorphic facial features, abnormal dentition, immune deficiency, severe hypoglycemia, and developmental delay (including autism).³⁸ Currently, most patients with TS die before reaching puberty. Although most cases of TS have been described as sporadic de novo occurrences, there have now been a few cases reported with somatic mosaicism that is associated with a less severe phenotype.³⁹ In such patients, for example, the *CACNA1C* mutation may be present in skeletal muscle but in only a minuscule amount or even completely absent in other types of cell in the human body (i.e., absent in heart, blood, lymphocytes, and other cell types), in which case the patient may have simple syndactyly but not an overt cardiac phenotype.

Genetic Basis for Timothy Syndrome. In 2004, Splawski and colleagues identified the molecular basis for this highly lethal arrhythmia disorder and coined it *Timothy syndrome* after Katherine Timothy, Drs. Keating's and Splawski's study coordinator, who meticulously phenotyped these cases.³⁸ Remarkably, in all 13 unrelated patients from whom DNA was available, Splawski and coworkers identified the same recurrent sporadic de novo missense mutation, G406R, in the alternatively spliced exon 8A of the *CACNA1C*-encoded cardiac LTCC ($Ca_v1.2$), which is important for excitation-contraction coupling in the heart and, like the cardiac sodium channel *SCN5A*, mediates an

inward depolarizing current in cardiomyocytes (see Table 32-1 and Fig. 32-1).³⁸ Through the mechanism of alternative splicing, the human LTCC consists of two mutually exclusive isoforms, one containing exon 8A and the other containing exon 8. A year later, Splawski and coworkers described two cases of atypical TS (TS2) with similar features of TS yet without syndactyly. As with other TS cases, these two atypical cases were identified as having sporadic de novo *CACNA1C* mutations not in exon 8A but rather in exon 8. One patient hosted a mutation analogous to the classic TS mutation G406R, whereas the other hosted a G402R missense mutation.⁴⁰ All three mutations confer gain of function to the LTCCs through impaired channel inactivation^{38,40} and reside very near the end of the S6 transmembrane segment of domain I in the beginning of the intracellular loop between domains I and II of the $\text{Ca}_v1.2$ alpha subunit. In 2012, Gillis and associates identified a novel *CACNA1C* mutation, A1473G, in a single patient with a prolonged QT interval, dysmorphic facial features, syndactyly, and joint contractures consistent with TS.⁴¹ Although this mutation has not yet been functionally characterized, interestingly, its topologic position (a few amino acids away from the S6 transmembrane segment of domain IV) in the channel architecture is very similar to the position of the three original TS mutations (S6 segment of domain I).

Short-QT Syndrome

Clinical Description and Manifestations of Short-QT Syndrome

Short-QT syndrome (SQTS), first described in 2000 by Gussak and colleagues, is associated with a short QT interval (usually ≤ 320 msec) on a 12-lead ECG, paroxysmal atrial fibrillation, syncope, and increased risk for SCD.⁴² Giustetto and coauthors analyzed the clinical features of 53 patients with SQTS from 29 families, the largest cohort studied to date, and found that 62% of the patients were symptomatic, with cardiac arrest being the most common symptom (31% of patients) and frequently the first manifestation of the disorder.⁴³ A fourth of the patients had a history of syncope, and almost 30% had a family history of SCD. Symptoms, including syncope or cardiac arrest, occurred most often during periods of rest or sleep. Almost a third had atrial fibrillation.⁴³ SCD was observed during infancy, thus suggesting a potential role for SQTS as a rare pathogenic basis for some cases of SIDS.⁴²

Genetic Basis for Short-QT Syndrome. SQTS is most often inherited in an autosomal dominant manner; however, some de novo sporadic cases have been described. To date, mutations in six genes (see Table 32-1) have been implicated in the pathogenesis of SQTS, including gain-of-function mutations in the potassium channel-encoding genes *KCNH2* (SQT1), *KCNQ1* (SQT2), and *KCNJ2* (SQT3) and loss-of-function mutations in *CACNA1C* (SQT4), *CACNB2b* (SQT5), and *CACNA2D1* (SQT6), which encode for the LTCC alpha, beta, and delta subunits, respectively (see Table 32-1 and Fig. 32-1).^{42,44,45} However, despite identification of these six SQTS susceptibility genes, it remains unknown what proportion of SQTS is expected to be SQT1 to SQT6 genotype positive and what proportion awaits genetic elucidation. It is estimated that more than 75% of SQTS cases remain genetically elusive.

Genotype-Phenotype Correlates in Short-QT Syndrome

Even though data are insufficient to clearly define genotype-phenotype correlations in SQTS, with probably fewer than 60 cases having been described in the literature to date, gene-specific ECG patterns are beginning to emerge. The typical ECG pattern consists of a QT interval of 320 milliseconds or less ($\text{QTc} \leq 340$ msec) and tall, peaked T waves in the precordial leads with either no or a short ST segment. The T waves tend to be symmetric in SQT1 but asymmetric in SQT2 to SQT4. In SQT2, inverted T waves can be observed. In SQT5, a BrS-like ST elevation in the right precordial lead may be observed.⁴²

Despite perhaps being premature because of a small sample size, a recent report has suggested that SQTS patients with *KCNH2* mutations have a shorter QT interval and a greater response to hydroquinidine therapy than do patients with a non-*KCNH2*-mediated SQTS.⁴⁶

Drug-Induced Torsades de Pointes

Clinical Description and Manifestations of Drug-Induced Torsades de Pointes

Drug-induced QT prolongation and/or drug-induced torsades de pointes (DI-TdP) are a constant concern for physicians prescribing particular drugs with the capacity for producing such unwanted and potentially life-threatening side effects (see Chapters 9 and 37). The estimated incidence of antiarrhythmic drug-induced TdP has ranged from 1% to 8%, depending on the drug and dose.⁴⁷ DI-TdP and subsequent sudden death are rare events; however, the list of potential “QT liability” or “torsadogenic” drugs is extensive and includes not only antiarrhythmic drugs such as quinidine, sotalol, and dofetilide but also many noncardiac medications such as antipsychotics, methadone, antimicrobials, antihistamines, and the gastrointestinal stimulant cisapride (see www.qtdrugs.org for a comprehensive list).⁴⁸

I_{Kr} Channel Blockers and the Repolarization Reserve

In addition to their intended function and their intended target of action, the vast majority of medications with a potential unwanted TdP-predisposing side effect are $\text{I}_{\text{Kr}}/\text{K}_{\text{v}}11.1$ channel blockers (also referred to as HERG channel blockers). In effect, QT-prolonging drugs create an “LQT2-like” phenotype through reduced repolarization efficiency and subsequent lengthening of the cardiac action potential.⁴⁹ However, I_{Kr} drug blockade alone does not appear sufficient to provide the potentially lethal TdP substrate. One particular thesis centers on the observation that cardiac repolarization relies on the interaction of several ion currents that provide some level of redundancy in protecting against extreme QT prolongation by “QT liability” drugs.⁴⁷ This so-called repolarization reserve may be reduced through anomalies in the repolarization machinery, namely, as a result of common or rare genetic variants in critical ion channels that produce subclinical loss of the repolarizing currents I_{Ks} and I_{Kr} .⁴⁷ In fact, recent studies have revealed that 10% to 15% of patients with DI-TdP host rare ion channel mutations.⁵⁰ A smaller study found potential LQTS susceptibility mutations in 40% of cases of seemingly isolated, drug-induced LQTS.⁵¹ Moreover, functional characterization of these mutations suggested that they were somewhat “weaker” than the loss-of-function mutations associated with classic, autosomal dominant LQTS, thus furthering the multiple-hit hypothesis that underlies the “reduced repolarization reserve.”

Common Ion Channel Polymorphisms and Drug-Induced Torsades de Pointes.

Among the common polymorphisms of the *KCNH2*-encoding I_{Kr} potassium channel, the K897T and R1047L polymorphisms have received the most attention (see Chapter 9). As noted in the review by Fitzgerald and Ackerman,⁴⁸ Paaonen and associates observed that T897-KCNH2 channels exhibit slower activation kinetics with a higher degree of inactivation, an alteration expected to decrease channel function and perhaps alter drug sensitivity because several commonly used drugs that inhibit I_{Kr} channel function bind preferentially to the inactivated state of the channel. These data suggest that T897 channels may genetically “reduce the repolarization reserve” and facilitate a proarrhythmic response that may be enhanced in the setting of I_{Kr} channel-blocking drugs when compared with wild-type K897 channels. In fact, K897T appears to affect the QTc response to ibutilide in a sex-specific manner. In a study by Sun and colleagues, as noted in a review by Schullze-Bahr,¹³ among 105 patients with atrial fibrillation treated with dofetilide, R1047L was overrepresented in those in whom DI-TdP developed in comparison to patients who were free of TdP. As well as these common potassium channel alpha subunit polymorphisms, three common polymorphisms (D85N-KCNE1, T8A-KCNE2, and Q9E-KCNE2) involving auxiliary beta subunits have been implicated in drug-induced susceptibility to arrhythmia.⁴⁸

In addition to genetic variants in major repolarizing channels, variants of the major depolarizing channel $\text{Na}_v1.5$ may provide a substrate for a proarrhythmic response in the setting of I_{Kr} -blocking drugs or in patients with other risk factors for DI-TdP. The most prominent channel polymorphism conferring susceptibility to arrhythmia in an ethnic-specific manner is S1103Y-SCN5A (originally annotated as the Y1102 variant). This polymorphism, seen in 13% of black Americans but not observed in any white or Asian controls (>1000 subjects), was overrepresented in arrhythmia cases (56.5%) in comparison to controls (13%) involving black Americans (odds ratio = 8.7).⁴⁷ S1103Y has been

found to produce subtle alterations in channel kinetics in heterologous expression studies when studied under basal conditions. However, functional and modeling studies have supported the potential for QT prolongation, reactivation of calcium channels early after depolarization, and arrhythmias, particularly in the setting of concomitant exposure to I_{Kr} -blocking drugs.

Recent genome-wide association studies have associated common variants of the *NOS1AP*-encoded nitric oxide synthase 1 adapter protein with QT interval duration. *NOS1AP* is a regulator of neuronal nitric oxide synthase (nNOS), which regulates intracellular calcium levels and myocyte contraction through its effect on LTCCs. Common SNPs in *NOS1AP* appear to be associated with drug-induced QT prolongation and ventricular arrhythmia.⁵² This association was most pronounced in patients taking amiodarone, currently one of the most common antiarrhythmic drugs. It has been hypothesized that genetic variants in *NOS1AP* that suppress expression of the gene may in turn result in increased LTCC currents and subsequent QT prolongation and that individuals with such variants may be at increased arrhythmogenic risk while taking amiodarone.⁵² However, although QT prolongation is observed routinely with amiodarone, DI-TdP attributed to amiodarone is exceedingly rare.

Additionally, genetic variation or individual differences in drug elimination or metabolism may contribute to individual risk for DI-TdP. For example, patients with a genetically mediated reduction in CYP3A enzymatic activity could be vulnerable to DI-TdP in the setting of I_{Kr} blockers that depend on the cytochrome P-450 enzyme CYP3A for its metabolism.¹³

THE OTHER CHANNELOPATHIES

Catecholaminergic Polymorphic Ventricular Tachycardia

Clinical Description and Manifestations of Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is a heritable arrhythmia syndrome that is classically manifested as exercise-induced syncope or sudden death, is predominately expressed in the young, and closely mimics the phenotypic byline of LQ1 but appears to be far more lethal.^{53,54} Like LQ1, swimming is a potentially lethal arrhythmia-precipitating trigger in CPVT. In fact, both LQ1 and CPVT have been shown to underlie several cases of unexplained drowning or near-drowning in young healthy swimmers.⁵⁵ However, CPVT is associated with a completely normal resting ECG (perhaps bradycardia and mild U waves) and is suspected on ECGs following either exercise or catecholamine stress testing in which significant ventricular ectopy is demonstrated that occasionally includes CPVT's pathognomonic arrhythmia of bidirectional VT.

Clinically, exercise-induced syncope and a QTc less than 460 milliseconds should always prompt first consideration of and need to rule out CPVT rather than the so-called concealed or normal-QT interval LQ1. Furthermore, exercise-induced

premature ventricular complexes in bigeminy are far more likely than the more specific but less sensitive finding of bidirectional VT.⁵⁶ CPVT is associated with a structurally normal heart. Once thought to be manifested only during childhood, more recent studies have suggested that age at onset can range from infancy to 40 years. The potential lethality of CPVT is illustrated by mortality rates of 30% to 50% by the age of 35 years and the presence of a positive family history of young (<40 years) SCD in more than a third of individuals with CPVT and in as many as 60% of families hosting *RyR2* mutations.⁵³ Moreover, approximately 15% of autopsy-negative cases of SUD in the young and some cases of SIDS have been attributed to CPVT.^{2,57}

Genetic Basis for Catecholaminergic Polymorphic Ventricular Tachycardia

Perturbations in key components of intracellular calcium-induced calcium release from the sarcoplasmic reticulum serve as the pathogenic basis for CPVT (see Chapter 33). Inherited in an autosomal dominant fashion, mutations in the *RyR2*-encoded cardiac ryanodine receptor/calcium release channel represent the most common genetic subtype of CPVT (CPVT1); such mutations account for 60% of clinically "strong" cases of CPVT (Fig. 32-5; also see Table 32-1). Gain-of-function mutations in *RyR2* lead to leaky calcium release channels, which results in excessive release of calcium, particularly during sympathetic stimulation, that can precipitate calcium overload, delayed depolarizations, and ventricular arrhythmias.⁵³ Again, most unrelated CPVT families are found to have their own unique *RyR2* mutations, and about 5% of unrelated mutation-positive patients host multiple putative pathogenic mutations.⁵⁸

RyR2 is one of the largest genes in the human genome, with 105 exons that transcribe/translate one of the largest cardiac ion channel proteins consisting of 4967 amino acid residues. Although there do not appear to be any specific mutation "hot spots," there are three regional hot spots or domains in which unique mutations reside (see Fig. 32-5). This observation has lent itself toward targeted genetic testing for *RyR2*

FIGURE 32-5 CPVT: a disorder of intracellular calcium handling. Perturbations in key components of the calcium-induced calcium release (CICR) mechanism responsible for cardiac excitation-contraction coupling are the pathogenic basis for CPVT. At the center of this mechanism is the *RyR2*-encoded cardiac ryanodine receptor/calcium release channel located in the membrane of the sarcoplasmic reticulum. Mutations in *RyR2* are clustered and distributed in three "hot spot" regions of this 4967-amino acid (AA) protein: domain I or the N-terminal domain (AA 57 to 1141), domain II or the central domain (AA 1638 to 2579), and domain III or the channel region (AA 3563 to 4967). PLB = phospholamban; PMCA = plasma membrane Ca^{2+} -adenosine triphosphatase (ATPase); SERCA 2a = sarcoendoplasmic reticulum Ca^{2+} -ATPase 2a.

(≈61 exons) rather than a comprehensive 105-exon scan. More than 90% of the *RyR2* mutations discovered to date represent missense mutations; however, perhaps as many as 5% of unrelated CPVT patients host large gene rearrangements consistent with large whole-exon deletions, akin to what has been observed in LQTS.⁵⁸ Even though genotype-phenotype correlations are very limited to date, a recent publication has suggested that family members hosting C-terminal (ion channel-forming domain) *RyR2* mutations may have a higher ventricular arrhythmia burden of nonsustained VT than individuals hosting N-terminal or central domain *RyR2*-localizing mutations.⁵⁹

Strikingly, nearly a third of “possible/atypical” patients with LQTS (QTc <480 msec) and exertion-induced syncope have also been identified as *RyR2*-mutation positive.⁵⁸ In fact, it has been reported that almost 30% of patients with CPVT have been misdiagnosed as having “LQTS with normal QT intervals” or “concealed LQTS,” thus indicating the critical importance of properly distinguishing between CPVT and LQTS at the clinical level because risk assessments and treatment strategies for these unique disorders may vary. Similarly, some patients in whom CPVT is diagnosed based on the presence of bidirectional VT during exercise have been identified with *KCNJ2* mutations that are associated with the rarely lethal ATS.³⁵ Misdiagnosis of ATS as the potentially lethal disorder CPVT may lead to more aggressive prophylactic therapy (i.e., cardioverter-defibrillator implantation) than necessary. Two autosomal recessive forms of CPVT have been identified that involve mutations in either the *CASQ2*-encoded calsequestrin-2 protein or *TRDN*-encoded triadin.^{60,61} Most recently, mutations in calmodulin-1 (*CALM1*) have been implicated as a cause of autosomal dominant CPVT; a single missense mutation was identified that segregated with a CPVT phenotype in a large Swedish pedigree (see Table 32-1).⁶²

Brugada Syndrome

Clinical Description and Manifestations of Brugada Syndrome

BrS is an heritable arrhythmia syndrome characterized by an ECG pattern consisting of coved-type ST-segment elevation (≥2 mm) followed by a negative T wave in the right precordial leads V₁ through V₃ (often referred to as a type 1 Brugada ECG pattern) and increased risk for sudden death resulting from episodes of polymorphic ventricular tachyarrhythmias.^{63,64} The penetrance and expressivity of the disorder are highly variable and range from life-long asymptomatic individuals to SCD during the first year of life. BrS is generally considered a disorder that involves young male adults, perhaps greatest in Southeast Asian males, with arrhythmogenic manifestations first arising at an average age of 40 years and sudden death typically occurring during sleep.^{65,66} In fact, sudden unexplained nocturnal death in young males is endemic in Southeast Asia and is now considered phenotypically, genetically, and functionally the same disorder as BrS.⁶⁴ However, BrS has also been demonstrated in children and infants.⁶⁷ In a 2007 population study of 30 children (<16 years of age) affected by BrS from 26 families, fever was the most common precipitating factor for arrhythmic cardiac events, including syncope and SCD.⁶⁷

Genetic Basis for Brugada Syndrome. BrS is inherited as an autosomal dominant trait; however, more than half of BrS cases may be sporadic. Approximately 20% to 30% of BrS cases stem from loss-of-function mutations in the *SCN5A*-encoded cardiac sodium channel (see Table 32-1 and Fig. 32-1) and are classified as Brugada syndrome type 1 (BrS1). In 2010, an international compendium of *SCN5A* mutations in patients referred for BrS genetic testing reported almost 300 distinct mutations in 438 of 2111 (21%) unrelated patients, and the mutation detection yield ranged from 11% to 28% across nine centers.⁶⁸ The yield of mutation detection may be significantly higher with familial forms than with sporadic cases. Schulze-Bahr and coworkers identified *SCN5A* mutations in 38% of their familial BrS cases as opposed to none in 27 sporadic cases ($P = 0.001$).⁶⁹ Most of the mutations were missense (66%), followed by frameshift (13%), nonsense, (11%), splice site (7%), and in-frame deletions/insertions (3%). Approximately 3% of genotype-positive patients host multiple putative pathogenic *SCN5A* mutations, and like the genotype-phenotype observations in LQTS,⁶ patients hosting multiple *SCN5A* mutations tend to be younger at diagnosis (29.7 ± 16 years) than those with a single mutation (39.2 ± 14.4 years).⁶⁸ Again, as with LQTS, there is no particular mutational hot spot, with almost 80% of the BrS-related *SCN5A* mutations occurring as “private” single-family mutations. However,

almost 10% of the 438 unrelated, *SCN5A* mutation-positive patients hosted one of four mutations: E1784K (14 patients), F861WfsX90 (11 patients), D356N (8 patients), and G1408R (7 patients).⁶⁸ Interestingly, the most commonly occurring BrS1 mutation, E1784K, has also been reported to be the most commonly seen LQTS-associated *SCN5A* mutation, thus illustrating how the same exact DNA alteration in a given gene can lead to two distinct cardiac arrhythmia syndromes, most likely as a result of other environmental or genetic modifying factors. In fact, E1784K represents the quintessential example of a cardiac sodium channel mutation with the capacity to provide a mixed clinical phenotype of LQTS, BrS, and conduction disorders.⁷⁰

In addition to pathogenic mutations in *SCN5A*, common polymorphisms may have a modifying effect on the disorder. As noted in the review by Antzelevitch and Nof,⁷¹ Bezzina and colleagues described an Asian-specific haplotype of six *SCN5A* promoter polymorphisms in nearly complete linkage disequilibrium that occurred with an allelic frequency of 22% and was comparatively absent in whites and blacks. These promoter region polymorphisms may modulate the variability in cardiac conduction and in part contribute to the higher prevalence of BrS observed in the Asian population. Brugada and coauthors provided data supporting the common polymorphism H558R as a modulator of the BrS phenotype, with the minor allele R558 providing a less severe clinical course in their 75 genotyped patients with BrS.⁶⁴ Patients homozygous for H558 had a longer QRS complex duration in lead II, higher J point elevation in lead V₂, and a higher “aVR sign” and tended to have more symptoms than H558R heterozygotes or R558 homozygotes.⁶⁴

Mutations have now been discovered in 13 BrS susceptibility genes in addition to *SCN5A* (see Table 32-1). Mechanistically, either decreases in the inward sodium or calcium currents or increases in the outward K_{4.3} potassium current produce the BrS phenotype through perturbation of either the respective channel alpha subunits or channel-interacting proteins (see Fig. 32-1).⁶⁵ For example, mutations in the glycerol-3-phosphate dehydrogenase 1-like protein encoded by *GPD1L* affect trafficking of the sodium channel to the plasma membrane, thus reducing the overall sodium current and giving rise to the BrS phenotype,⁷² whereas mutations involving the LTCC alpha and beta subunits encoded by the *CACNA1C* and *CACNB2b* genes, respectively, were implicated in approximately 10% of BrS cases.⁷³ However, on closer examination of this seminal discovery, a tight link between calcium channel-mediated disease and the clinical phenotype of BrS with a concomitant short QT interval is evident, with 50% of patients with BrS/short QT interval hosting a mutation in the LTCC subunit. In fact, in 2012, Crotti and colleagues performed the first comprehensive mutational analysis of a large cohort of unrelated patients with BrS, and although they identified *SCN5A* mutations in 16% of the cohort, only 1.5% of the BrS cases had a mutation in one of the LTCC subunit genes in the absence of a short QT interval.⁷⁴ Importantly, the genetic cause of more than two thirds of clinically diagnosed cases of BrS remains elusive, thus suggesting a high degree of genetic heterogeneity for this disorder. This degree of genetic elusiveness also begs the question of whether most BrS is a genetically heterogeneous monogenic disorder or in fact a congenital heart defect/developmental disorder involving the epicardial right ventricular outflow tract.⁷⁵

Genotype-Phenotype Correlates in Brugada Syndrome

Because most BrS cases are genetically elusive, genotype-phenotype correlations in BrS have not been analyzed to the same degree as in LQTS. *SCN5A* mutations are associated with a higher incidence of conduction abnormalities in patients with BrS, and the presence of a long PQ interval may be indicative of *SCN5A*-mediated BrS1, whereas the presence of a short QT interval (QTc <350 msec) may be indicative of LTCC-mediated BrS pathology. In fact, Crotti and coauthors reported that although fewer than 10% of patients with a PQ interval of less than 200 milliseconds had a positive *SCN5A* genetic test, the yield was almost 40% in patients with a PQ interval of 200 milliseconds or more.⁷⁴ Interestingly, young males with BrS (<20 years, 83%) had a significantly higher *SCN5A* mutation detection rate than did males aged 20 to 40 years (21%) and those older than 40 years (11%, $P < 0.0001$).⁷⁴ In addition, patients with BrS1 and nonsense, frameshift, or premature truncation-causing mutations exhibited a more severe phenotype.⁷⁶ Unlike genetic testing for LQTS, in which the triad of diagnostic, prognostic, and therapeutic impact has been fulfilled, genetic testing for BrS is currently limited by its lower yield (25% for BrS versus 75% for LQTS) and relative absence of a therapeutic contribution from knowledge of the genotype.^{31,77}

Early Repolarization Syndrome

Clinical Description and Manifestations of Early Repolarization Syndrome

The early repolarization (ER) pattern is characterized by the ECG finding of elevation (≥ 1 mm above baseline) of the QRS-ST junction (the so-called J point) manifested as either QRS slurring (at the transition of the QRS to the ST segment) or notching (a positive deflection inscribed on the terminal S wave), ST-segment elevation with upper concavity, and prominent T waves in two or more contiguous leads.⁷⁸ The prevalence of the ER pattern in the general population has been reported to range from less than 1% to 13%, depending on age, sex, race, and the criteria for J point elevation.⁷⁸ This ECG phenomenon has long been considered an innocuous variant in healthy individuals. However, Haissaguerre and colleagues noted that J point elevation (≥ 1 mm above baseline) on inferolateral ECG leads was significantly overrepresented (31%) and greater in magnitude in 206 case subjects who experienced cardiac arrest secondary to idiopathic ventricular fibrillation (IVF) than in 412 controls (5%, $P < 0.001$) matched for age, sex, race, and level of physical activity.⁷⁹ Patients with ER were more often males and had a personal history of syncope or cardiac arrest during sleep than did those without an ER pattern.⁷⁹ Similarly, Rosso and associates saw an overrepresentation of J point elevation in their 45 patients with IVF in comparison to controls (45% versus 13%, $P = 0.001$), with the same observation of a male preponderance in those with ER.⁸⁰

In a community-based general population of 10,864 middle-aged (30 to 59 years old, 52% male) Finnish subjects, Tikkanen and colleagues identified 630 subjects overall (5.8%) with a J point elevation of at least 0.1 mV.⁸¹ The overall prevalence of the ER pattern was reduced to just 0.33% when considering a J point elevation of 0.2 mV or higher. After a 30-year follow-up with the endpoint being cardiac death, Tikkanen and colleagues noted that when compared with subjects without a J point elevation, subjects with ER (J point ≥ 0.1 mV) in the inferior leads had an increased risk for both cardiac death (adjusted relative risk [ARR] = 1.28; 95% confidence interval [CI] = 1.04 to 1.59; $P = 0.03$) and arrhythmias (ARR = 1.43; 95% CI = 1.06 to 1.94; $P = 0.03$) and that this risk was further elevated (cardiac death ARR = 2.98; 95% CI = 1.85 to 4.92; $P < 0.001$; arrhythmia ARR = 2.92; 95% CI = 1.45 to 5.89; $P < 0.001$) with increasing elevation (≥ 0.2 mV) of the J point. However, an ER pattern localizing to only the lateral leads did not show a statistically significant association with increased risk for arrhythmic cardiac death.⁸¹ Obviously, the vexing clinical conundrum with respect to this inferolateral early repolarization syndrome (ERS) is that of distinguishing potentially lethal ERS from the all too often observed juvenile ER pattern seen in healthy subjects, particularly healthy athletes.

Genetic Basis for Early Repolarization Syndrome. The inclination for a genetic basis for ERS stems from Haissaguerre and colleagues' observation that 16% of their patients with IVF and an ER pattern had a family history of SUD.⁷⁹ The first gene to be implicated in ERS was described by Haissaguerre and associates, who reported finding a rare, functionally uncharacterized, missense mutation (S422L) in the *KCNJ8*-encoding pore-forming subunit Kir6.1 of the adenosine triphosphate-sensitive potassium channel in a 14-year-old girl with IVF.⁸² Since then, this same mutation has been described in additional cases of BrS and ERS and has been shown to have a gain of function in electrophysiologic phenotype.^{83,84} In 2010, Burashnikov and colleagues implicated the LTCC α -1 (*CACNA1C*), β -2 (*CACNB2b*), and α -2-delta (*CACNA2D1*) subunit-encoding genes in the pathogenesis of ERS with their identification of mutations in 4 of 24 (16.7%) ERS index cases⁸⁵; however, not all these genetic variants have been characterized functionally, and some may represent a rare VUS.

Progressive Cardiac Conduction Disease

Clinical Description and Manifestations of Progressive Cardiac Conduction Disease

Cardiac conduction disease (CCD) causes a potentially life-threatening alteration in normal impulse propagation through the cardiac conduction system. CCD can be a result of a number of

physiologic mechanisms ranging from acquired to congenital, with or without structural heart disease. Progressive cardiac conduction disease (PCCD), also known as Lev-Lenègre disease, is one of the most common cardiac conduction disturbances in the absence of structural heart disease and is characterized by a progressive (age-related) alteration in impulse propagation through the His-Purkinje system, with right or left bundle branch block and widening of the QRS complex leading to complete AV block, syncope, and occasionally sudden death.⁶⁶

Genetic Basis for Progressive Cardiac Conduction Disease. As noted in a review by Raun and associates,⁶⁶ Schott and coworkers further expanded the spectrum of loss-of-function *SCN5A* disease in 1999 with the inclusion of familial PCCD. They identified a splice site *SCN5A* mutation (c.3963+2 T>C) associated with an autosomal dominant inheritance pattern in a large French family. Since then, investigators have identified more than 30 PCCD-associated mutations in *SCN5A*; additionally, mutations in *SCN1B* can cause BrS with conduction disease. These mutations result in a loss-of-function phenotype through reduced current density and enhanced slow inactivation of the channel. As with most loss-of-function *SCN5A* diseases, the phenotypic expression of PCCD can be complex and is often accompanied by a concomitant BrS or BrS-like phenotype. In fact, Probst and coworkers showed that PCCD is the prevailing phenotype in BrS-associated *SCN5A* mutation carriers, in whom the penetrance of conduction defects was 76%.⁶⁷

In 2009, Meregalli and colleagues demonstrated that the *SCN5A* mutation type can have a profound effect on the severity of PCCD and BrS.⁷⁶ Studying 147 individuals hosting one of 32 different *SCN5A* mutations, Meregalli and coworkers found that patients with either a premature truncation mutation (M_{tr} , i.e., nonsense or frameshift) or a severe loss-of-function missense mutation ($M_{inactive}$, $>90\%$ reduction in peak I_{Na}) had a significantly longer PR interval than did patients with missense mutations causing less impairment of the sodium current (M_{active} , $\leq 90\%$ reduction). Furthermore, patients with a truncation mutation had significantly more episodes of syncope than did those with an "active" mutation (M_{active}).⁷⁶ These data suggest that mutations with more deleterious loss of sodium current produce a more severe phenotype of syncope and conduction defect, thus providing the first evidence for intragenotype risk stratification associated with *SCN5A* loss-of-function disease.

Most recently, gain-of-function mutations (E7K, R164W, A432T, and G844D) in the *TRPM4*-encoded transient receptor potential melastatin type 4 ion channel have been implicated as a cause of autosomal dominant isolated CCD and progressive familial heart block type 1 (PFHB1) following linkage analysis and subsequent mutational analysis of *TRPM4* in four different large multigenerational pedigrees, thus identifying an essential role for calcium-activated nonselective cation channel activity in the cardiac conduction system.^{86,87}

When CCD is associated with a concomitant LQTS phenotype, the QRS interval is usually narrow and the conduction defect is commonly an intermittent 2:1 AV block. Patients with LQT2, TS1, or ATS1 may also have dysfunctional AV conduction.

Sick Sinus Syndrome

Clinical Description and Manifestations of Sick Sinus Syndrome

Sinus node dysfunction (SND) or sick sinus syndrome (SSS) manifested as inappropriate sinus bradycardia, sinus arrest, atrial standstill, tachycardia-bradycardia syndrome, or chronotropic incompetence is the principal reason for pacemaker implantation and has been attributed to dysfunction of the sinoatrial (SA) node^{37,66} (see Chapter 37). SSS commonly occurs in the elderly (1 in 600 cardiac patients >65 years) with acquired cardiac conditions, including cardiomyopathy, congestive heart failure, ischemic heart disease, or metabolic diseases. However, a significant number of patients have no identifiable cardiac anomalies or cardiac conditions underlying their sinus node dysfunction ("idiopathic SND"), which can occur at any age, including in utero.³⁷ Additionally, familial forms of idiopathic SND consistent with autosomal dominant inheritance with reduced penetrance and recessive forms with complete penetrance have been reported.⁶⁶

Genetic Basis for Sick Sinus Syndrome. Mutational analysis of small cohorts and case reports of patients with idiopathic SSS have thus far implicated three genes: *SCN5A*, *HCN4*, and *ANKB* (see Table 32-1). To date, 15 SSS-associated mutations have been reported in *SCN5A*.^{66,88}

The mutations produced either nonfunctional sodium channels through loss of expression or channels with mild to severe loss of function through an altered biophysical mechanism of the channel.⁸⁸ As noted in a review by Raun and associates,⁶⁶ in 2003, basing their work on previous observations of arrhythmias and conduction disturbances, Benson and colleagues examined *SCN5A* as a candidate gene for congenital SSS in 10 pediatric patients from seven families in whom SSS was diagnosed during the first decade of life. They identified compound heterozygote mutations (T220I + R1623X, P1298L + G1408R, and delF1617 + R1632H) in five individuals from three of the seven families, thus implicating *SCN5A* in autosomal recessive SSS. Not surprisingly, many of the *SCN5A*-positive patients displayed a mixed phenotype consisting of SSS, BrS, and/or CCD. The expressivity of the mixed phenotype can be highly variable within affected families. In 2007, the case of a 12-year-old boy with SSS, CCD, and recurrent VT was presented. The patient was identified with an L1821fsX10 frameshift mutation that displayed a unique channel phenotype of 90% reduced current density (consistent with BrS/SSS/CCD), yet an increase in the late sodium current relative to the peak current (consistent with LQT3) in the channels that are expressed. As illustrated by this family, in which the mutation was present in six asymptomatic family members and two displayed only mild ECG phenotypes, this disorder is often associated with incomplete or low penetrance.

Two loss-of-function mutations in the hyperpolarization-activated cyclic nucleotide-gated channel 4 gene *HCN4* have been identified in two cases of idiopathic SND. The *HCN4* gene encodes the so-called I_f or pacemaker current and plays a key role in automaticity of the sinus node. In one study, a heterozygous single nucleotide deletion (c.1631delC) creating a frameshift mutation (P544fsX30) with early truncation of the protein was identified in a patient with idiopathic SND, and in a second study, another patient with idiopathic SND had a missense mutation (D553N) that results in abnormal trafficking of the pacemaker channel.⁸⁹ Interestingly, although the frameshift mutation identified in a 66-year-old woman produced a mild phenotype associated with sinus rhythm during exercise, the D553N missense mutation identified in a 43-year-old woman was associated with severe bradycardia, recurrent syncope, QT prolongation, and polymorphic VT (TdP), thus suggesting the potential for lethality in *HCN4*-mediated disease.⁸⁹ Whether the preliminary 10% to 15% yield of defective *HCN4*-encoded pacemaker channels in idiopathic SND derived from the two small cohorts is durable will require further studies involving much larger cohorts.

In 2008, Le Scouarnec and coauthors reported the genetic and molecular mechanism involving *ANK2* (also known as *ANKB*)-encoded ankyrin-B in two large families with highly penetrant and severe SND.⁹⁰ Ankyrin-B is essential for normal membrane organization of the ion channels and transporters in cardiocytes within the SA node and is required for proper physiologic cardiac pacing. Dysfunction of the ankyrin-B-based trafficking pathway causes abnormal electrical activity in the SA node and SND.⁹⁰ Similar to the sodium channel, variants in *ANK2* cause a variety of cardiac dysfunctions.

CONCLUSIONS

This relatively new discipline of the heritable arrhythmia syndromes/cardiac channelopathies has exploded over the past decade. The pathogenic insights into the molecular underpinnings for nearly all these syndromes have matured through the entire continuum of research from discovery, translation, and most recently, incorporation into clinical practice. This bench-to-bedside maturation now requires learned interpretation of the available genetic tests for these syndromes and a clear understanding of the diagnostic, prognostic, and therapeutic implications associated with genetic testing for these channelopathies.

FUTURE PERSPECTIVES

The emergence of next-generation sequencing platforms and systems biology bioinformatics algorithms is providing new tools to efficiently interrogate an individual's entire genome or exome (entire amino acid-encoding region of the genome) in a single reaction. This highly proficient technology effectively provides a list of every single nucleotide substitution and small insertion/deletion (common or rare,

benign or pathogenic) for every gene in a patient's genome and is crucial for the current and next phase of new gene discovery within even small currently genotype-negative pedigrees. It is through the current advanced sequencing technologies and systems biology bioinformatics algorithms and those on the horizon that we will soon be able to close the genetic gap in our understanding of these potentially lethal yet highly treatable cardiac arrhythmia syndromes.

In addition, recent advances in cellular programming have provided new avenues for understanding the cause of complex diseases. The biomedical promise of human induced pluripotent stem cell-generated cardiomyocytes derived from the patient's own skin biopsy specimen (fibroblast) is enormous and may hold significant promise in cardiac research involving disease models, personalized drug development, and key questions about the reduced penetrance and variable expressivity that is common in these cardiac channelopathies.

ANATOMY OF THE CARDIAC CONDUCTION SYSTEM

Sinoatrial Node

In humans, the sinoatrial node is a spindle-shaped structure composed of a fibrous tissue matrix with closely packed cells. It is 10 to 20 mm long and 2 to 3 mm wide and thick and tends to narrow caudally toward the inferior vena cava. It lies less than 1 mm from the epicardial surface, laterally in the right atrial sulcus terminalis at the junction of the superior vena cava and right atrium (**Figs. 33-1 and 33-2**). The artery supplying the sinoatrial node branches from the right (55% to 60% of the time) or the left (40% to 45%) circumflex coronary artery and approaches the node from a clockwise or counterclockwise direction around the junction of the superior vena cava and right atrium.

Cellular Structure. Cells from the sinoatrial node region exhibit a wide variety of morphologic features, including spindle- and spider-shaped cells, rod-shaped atrial cells with clear striations, and small round cells corresponding to endothelial cells.¹ Only the spindle- and spider-shaped cells exhibit the typical electrophysiologic characteristics of pacemaker cells, including the hyperpolarization-activated current I_h ¹ and spontaneous beating under physiologic conditions.²

Function. The ionic mechanism underlying sinoatrial node cell automaticity has been controversial. Some groups promote a model in which hyperpolarization-activated cyclic nucleotide-gated (HCN) ion channels are the main regulator of the heart rate, whereas other groups promote a model in which intracellular Ca^{2+} oscillations affecting Ca^{2+} -sensitive ion channels and ion transporters in the outer membrane give rise to diastolic membrane depolarizations, which then trigger a propagating sinoatrial node action potential^{3,4} (see later). Similarly, the mechanism of entrainment that enables synchronization of the electrical activity of multiple individual sinoatrial node cells to give rise to discharge of the sinoatrial node has been uncertain. Very probably, no single cell in the sinoatrial node serves as the pacemaker. Rather, sinoatrial nodal cells function as electrically coupled oscillators that discharge synchronously. The interaction depends on the degree of coupling and the electrophysiologic characteristics of the individual sinoatrial node cell. The resulting rate is not just a simple average of each of the cells. With an individual pacemaker cell coupled to an average of five other cells, each with potentially different electrophysiologic properties, the resulting discharge rate is not obvious. Functioning of the sinoatrial node as a pacemaker requires a delicate balance of intercellular electrical coupling. Excess electrical coupling depresses sinoatrial node automaticity because the sinoatrial node membrane potential is damped by the surrounding atrial myocardium to a more negative potential than the normal maximal diastolic potential, thereby inhibiting spontaneous diastolic depolarization (see **Fig. 33-18**). Too little coupling can prevent transmission of impulses to the adjacent atrial muscle. Restriction of the hyperpolarizing influence of the atrial muscle on the sinoatrial node while maintaining exit of impulses into the adjacent atrial myocardium is achieved by the composition and

spatial organization of connexins, proteins that form gap junction channels responsible for intercellular ion fluxes (see later, **Intercalated Discs**). Connexins 40 and 45, but not connexin 43, are expressed in the central sinoatrial node (**Fig. 33-3**). The major part of the crista terminalis–sinoatrial node border exhibits a sharp demarcation boundary of connexin 43–expressing atrial myocytes and connexin 40/45–expressing myocytes. On the endocardial side, a transitional zone (paranodal area; see **Fig. 33-2**) exists between the crista terminalis and the peripheral node in which connexins 45 and 43 are colocalized. This colocalization of different connexin isoforms raises the possibility that individual gap junctional channels in the transitional zone are formed by more than one connexin isoform.²

These disparate connexin phenotypes may create specific types of hybrid channels with rectifying electrical properties that ensure the maintenance of sinoatrial node pacemaker activity but diminish electrotonic interference from the atrial muscle.⁵ At the level of the intact sinoatrial node in situ, more recent studies combining immunohistochemistry and high-resolution optical mapping of action potentials have provided structural and functional evidence of the existence of discrete exit pathways that electrically connect the sinoatrial node and atria in canines, whose three-dimensional sinoatrial node structure closely resembles that of humans. In this model (**Fig. 33-4**), electrical excitation during sinoatrial rhythm originates in the central portion of the sinoatrial node and spreads bidirectionally at low speed (1 to 14 cm/sec) within the sinoatrial node, with failure to conduct laterally to the crista terminalis and interatrial septum. After a conduction delay of approximately 50 milliseconds within the sinoatrial node, the impulse reaches the atrial myocardium via two main superior or inferior exit pathways located a few millimeters from the leading pacemaker site. The ellipsoidal sinoatrial node is thus functionally insulated from the adjacent working myocardium. This insulation coincides with the lack of connexin 43 expression and the presence of connective tissue and coronary arteries at the sinoatrial border (see **Fig. 33-4C-F**).⁶ The intranodal location of the primary pacemaking site is not fixed but rather appears to shift under varying conditions (e.g., sympathetic stimulation; see later in this chapter).

A number of experimental studies have investigated the usefulness of gene delivery– or cell-based approaches to generate biologic pacemakers in the mammalian heart. Gene-based techniques included transduction of in situ left ventricular cardiomyocytes with genes encoding a dominant-negative inwardly rectifying potassium channel or isoforms of the HCN channel. Cell-based approaches have used human induced pluripotent stem cell (iPSC)-derived pacemaker-like cardiomyocytes and mesenchymal stem cells ectopically expressing HCN isoform 2. Clinical translatability of these approaches will require additional experimental testing.⁷

Innervation. The sinoatrial node is densely innervated by postganglionic adrenergic and cholinergic nerve terminals.⁸ Discrete vagal efferent pathways innervate both the sinoatrial and atrioventricular (AV) regions of the dog and nonhuman primate. Most efferent vagal fibers to the atria appear to converge first at a single fat pad between the medial portion of the superior vena cava and the aortic root, superior to the right pulmonary artery; the fibers then project onto two other fat pads found at the junction of the inferior vena cava and

left atrium and the junction of the right pulmonary vein and atrium and subsequently project to both atria. Vagal fibers to the sinoatrial and AV nodes also converge at the superior vena cava–aortic root fat pad before projection to the right pulmonary vein and inferior vena cava fat pads.⁸ Although the sinoatrial nodal region contains amounts of norepinephrine equivalent to those in other parts of the right atrium, acetylcholine, acetylcholinesterase, and choline acetyltransferase (the enzyme necessary for the synthesis of acetylcholine) have been found in greatest concentration in the sinoatrial node, with the next highest concentration located in the right and then the left atrium. The concentration of acetylcholine in the ventricles is only 20% to 50% of that in the atria.

Neurotransmitters modulate the discharge rate of the sinoatrial node by stimulation of beta-adrenergic and muscarinic receptors. Both beta₁ and beta₂ adrenoceptor subtypes are present in the

FIGURE 33-1 The human sinus node. This photograph, taken in the operating room, shows the location of the normal cigar-shaped sinus node along the lateral border of the terminal groove at the junction of the superior vena cava and atrium (arrowheads). (From Anderson RH, Wilcox BR, Becker AE: *Anatomy of the normal heart*. In Hurst JW, Anderson RH, Becker AE, Wilcox BR [eds]: *Atlas of the Heart*. New York, Gower, 1988, p 1.2.)

sinoatrial node. Human sinoatrial nodes contain more than a threefold greater density of beta-adrenergic and muscarinic cholinergic receptors than adjacent atrial tissue does. The functional significance of beta adrenoceptor subtype diversity in the sinoatrial node is unclear. Binding of receptor agonists released from sympathetic nerve terminals causes a positive chronotropic response through a beta₁ receptor-activated pathway involving the stimulatory guanosine triphosphate (GTP) regulatory protein (G_s), activation of adenylyl cyclase, intracellular accumulation of cyclic adenosine monophosphate (cAMP), stimulation of cAMP-dependent protein kinase A, and phosphorylation of ion-handling proteins, which ultimately results in an increased sinoatrial node discharge rate (for a more detailed description of the ionic mechanisms underlying the acceleration of sinoatrial node action potential firing see later in this chapter).⁹ The negative chronotropic response of vagal stimulation is mediated by acetylcholine binding to and ensuing activation of M₂ muscarinic receptors.

In addition to its negative chronotropic effect, acetylcholine also prolongs intranodal conduction time, at times to the point of sinoatrial nodal exit block. Acetylcholine increases whereas norepinephrine decreases refractoriness in the center of the sinoatrial node. The phase (timing) in the cardiac cycle at which vagal discharge occurs and the background sympathetic tone importantly influence vagal effects on the sinus rate and conduction (see later). After cessation of vagal stimulation, sinoatrial nodal automaticity may accelerate transiently (postvagal tachycardia). The neurotransmitters neuropeptide Y (NPY) and vasoactive intestinal peptide (VIP) are localized in sympathetic and

FIGURE 33-2 Masson trichrome-stained section through the human sinus node region. The node (red dashed line) is identified on the basis of the presence of the sinus node artery and the large amount of connective tissue (stained blue; myocytes stained purple-pink). The section also reveals the presence of a paranodal area (green dashed line) that is composed of loosely packed myocytes and sandwiched between the crista terminalis (yellow dashed line) and the sinus node. (From Chandler NJ, Greener ID, Tellez JO, et al: *Molecular architecture of the human sinus node*. *Circulation* 119:1562, 2009. By permission of the American Heart Association.)

FIGURE 33-3 Sections through the sinoatrial node double-labeled with connexin 45 (Cx45)/Cx43 (left) and Cx40/Cx43 (right). Regions positive for Cx40/Cx43 (small punctate green signals) showing no detectable Cx43 signal (red) are sharply demarcated from adjacent Cx43-expressing regions of the crista terminalis. A zone of connective tissue (asterisks) contributes to separation between the zones, although elsewhere (arrow) the zones seem to be more closely approximated. (From Coppen SR, Kodama I, Boyett MR, et al: *Connexin45, a major connexin of the rabbit sino-atrial node, is co-expressed with connexin43 in a restricted zone at the nodal-crista terminalis border*. *J Histochem Cytochem* 47:907, 1999.)

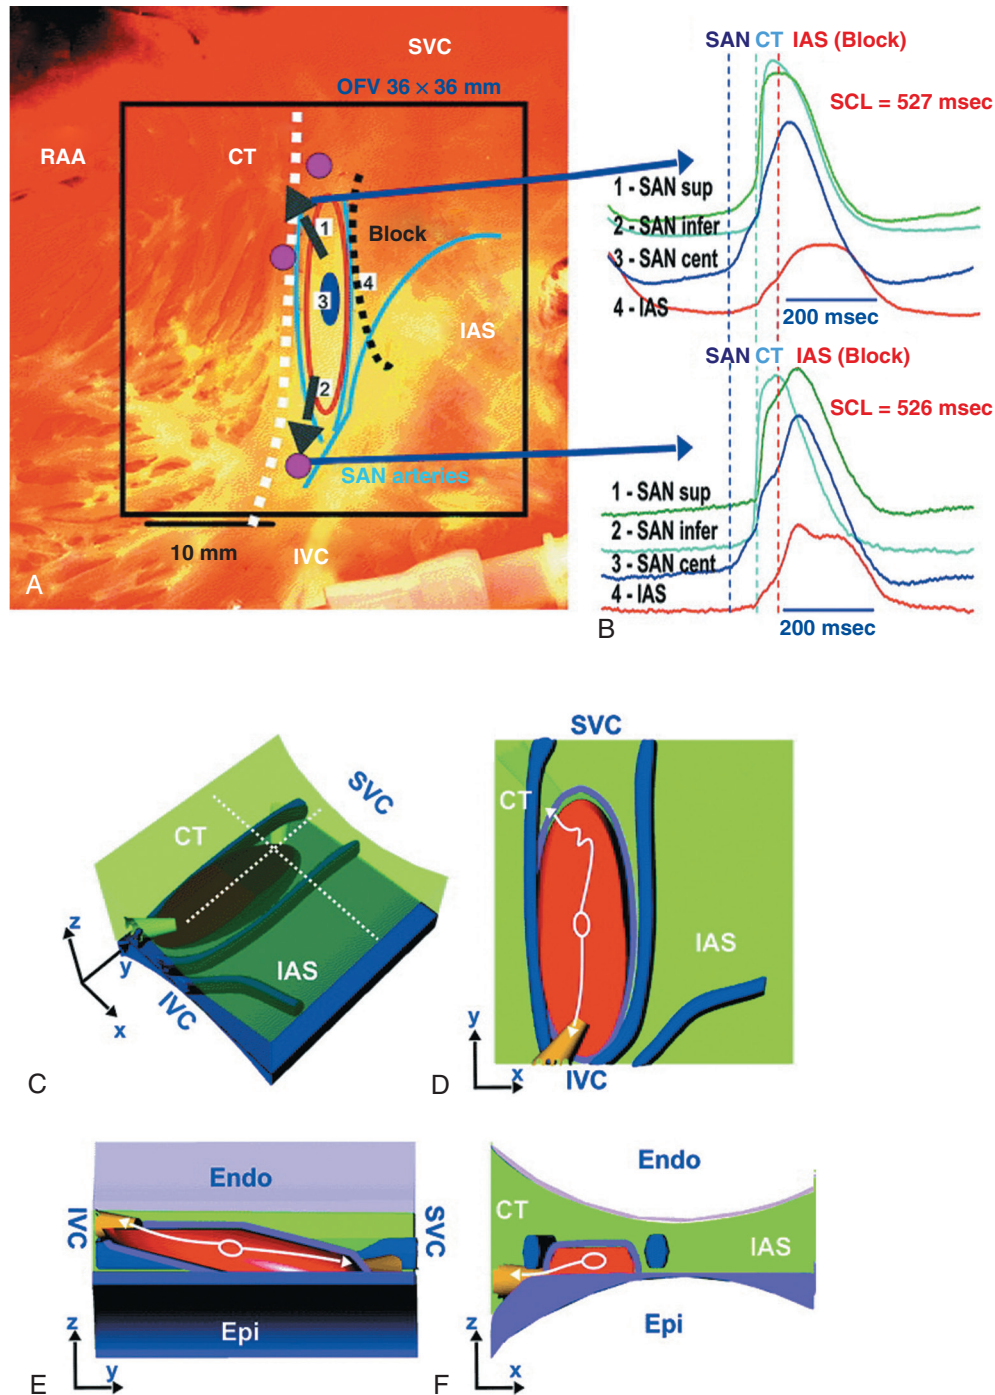

FIGURE 33-4 Endocardial optical voltage mapping in a canine right atrial preparation. **A**, Photograph of the endocardial aspect of the preparation. CT = crista terminalis; IAS = interatrial septum; OFV = optical field of view from which the optical recordings were taken; RAA = right atrial appendage; SVC and IVC = superior and inferior vena cava, respectively. The sinoatrial node (SAN; red oval) is flanked by branches of the SAN artery (drawn schematically in light blue). **B**, Optical action potentials recorded during sinus rhythm from sites 1 through 4 depicted in the photograph in **A**. Sites 1 and 2 are from the superior (SAN sup) and inferior (SAN infer) part of the SAN, near the SAN exit pathways. Site 3 is from the leading pacemaker site (SAN cent), and site 4 is from the IAS block zone. Electrical excitation originates in the central portion of the SAN (dark blue oval in **A**) and spreads bidirectionally within the SAN, with failure to conduct in a perpendicular direction into the IAS and CT. After a conduction delay of approximately 50 milliseconds within the SAN, excitation reaches the atrial myocardium via superior (upper tracings in **B**) or inferior (lower tracings in **B**) sinoatrial exit pathways approximately 9 mm from the leading pacemaker site. The ellipsoidal SAN structure (red line in **A**) is functionally insulated from the atrial myocardium, as indicated by the dashed white and black lines in **A**, respectively, except for two (inferior and superior) exit pathways. Vertical dashed lines indicate the beginning of SAN, CT, and IAS activation. SCL denotes sinus cycle length. Numbers to the left of the optical action potential tracings correspond to the respective recording sites in the photograph in **A**. **C-F**, Three-dimensional model of the SAN. The green area represents the myocardium. The fibrotic tissue (purple) and coronary arteries (blue) enclose the SAN (red). The initial excitation during sinus rhythm is shown by a white oval. The arrows denote the two main directions of propagation of the impulse within the SAN. The yellow bundles show the sinus node exit pathways. **C** and **D** show side and top projections, respectively. **E** and **F** show cross sections in the z-y and z-x plane, respectively. (From Fedorov VV, Schuessler RB, Hemhill M, et al: Structural and functional evidence for discrete exit pathways that connect the canine sinoatrial node and atria. *Circ Res* 104:915, 2009. By permission of the American Heart Association.)

parasympathetic nerve terminals, respectively. VIP reversibly increases I_i , whereas NPY reversibly decreases I_i . The role of other peripheral neurotransmitters (such as calcitonin gene-related peptide, substance P) in controlling sinoatrial node electrophysiology is unclear.

Atrioventricular Junctional Area and Intraventricular Conduction System

Atrioventricular Node

Based on histology and immunolabeling, the normal AV junctional area (Figs. 33-5 and 33-6) is composed of multiple distinct structures, including transitional tissue, inferior nodal extension, compact portion, penetrating bundle, His bundle, atrial and ventricular muscle, central fibrous body, tendon of Todaro, and valves.^{10,11} Figure 33-7A, B shows a computer-generated three-dimensional reconstruction of the AV junctional area in a rabbit heart. At the level of the AV junction, the tract of nodal tissue is divided into two major components, the inferior nodal extension and the penetrating bundle (red and purple areas, respectively, in Fig. 33-7A, B). The inferior nodal extension is located between the coronary sinus and the tricuspid valve, and the end of the inferior nodal extension is covered by transitional tissue (light green area in Fig. 33-7A, B). The small myocytes in the inferior nodal extension are dispersed among connective tissue and do not express connexin 43, whereas myocytes in the transitional zone do express connexin 43; however, unlike the connexin 43-positive atrial myocytes in the working myocardium, they are loosely packed between collagen septa. The inferior nodal extension is continuous with the penetrating bundle, which penetrates the fibrous tissue separating the atria and ventricles and emerges in the ventricles as the bundle of His. Both structures are covered by connective tissue (sheaths in Fig. 33-7A) and are therefore enclosed. Myocytes in the penetrating bundle express connexin 43 and are dispersed among connective tissue. A tract of connexin 43-positive nodal tissue projects into the connexin 43-negative inferior nodal extension.

The compact portion of the AV node (yellow area in Fig. 33-7A, B) is a superficial structure lying just beneath the right atrial endocardium, anterior to the ostium of the coronary sinus, and directly above the insertion of the septal leaflet of the tricuspid valve. It is at the apex of a triangle formed by the tricuspid annulus and the tendon of Todaro (blue area in Fig. 33-7A, B), which originates in the central fibrous body and passes posteriorly through the atrial septum to continue with the eustachian valve (see Figs. 33-5 and 33-6A). The term *triangle of Koch*, however, has to be used with caution because histologic studies of anatomically normal adult hearts have demonstrated that the tendon of Todaro, which forms one side of the triangle of Koch, is absent in about two thirds of hearts. The compact node is located at the junction where the connexin 43-negative nodal tissue (red area in Fig. 33-7A, B) meets the connexin 43-positive nodal tissue (purple area in Fig. 33-7A, B). Myocytes in the nodal portion are small and weakly positive for connexin 43. In 85% to 90% of human hearts, the arterial supply to the AV node is derived from a branch of the right coronary artery that originates at the posterior intersection of the AV and interventricular grooves (crux). A branch of the circumflex coronary artery provides the arterial supply to the AV node in the remaining hearts. Fibers in the lower part of the AV node may exhibit automatic impulse formation.¹¹ The main function of the AV node is to delay transmission of atrial impulses to the ventricles, thereby coordinating atrial and ventricular contractions (Fig. 33-7C, D). During normal anterograde AV conduction, the action potential propagates from the sinoatrial node through atrial working myocardium (the existence of specialized internodal conduction pathways has been controversial) and enters the tract of nodal tissue at two points (see Fig. 33-7C; see also Video 33-1). The first point is at the end of the inferior nodal extension (next to the penetrating bundle) via the transitional tissue. This conduction pathway most likely corresponds to the fast-pathway route previously observed in electrical mapping experiments.¹¹ Second, the action potential enters toward the beginning of the inferior nodal extension. This conduction pathway probably constitutes the slow-pathway route. The action potential cannot enter the nodal tissue at other tissue points because the nodal and atrial tissues are isolated from each other by a vein along this length

FIGURE 33-5 A, Photograph of a normal human heart showing the anatomic landmarks of the triangle of Koch. This triangle is delimited by the tendon of Todaro superiorly, by the fibrous commissure of the flap guarding the openings of the inferior vena cava and coronary sinus, by the attachment of the septal leaflet of the tricuspid valve inferiorly, and by the mouth of the coronary sinus at the base. B, The stippled area adjacent to the central fibrous body is the approximate site of the compact AV node. (From Janse MJ, Anderson RH, McGuire MA, et al: "AV nodal" reentry: I. "AV nodal" reentry revisited. *J Cardiovasc Electrophysiol* 4:561, 1993.)

of tissue (dark green area in Fig. 33-7B, C). From the two entry points, the action potentials propagate both anterogradely and retrogradely along the inferior nodal extension and eventually annihilate each other. The action potential entering the nodal tract via the transitional zone also propagates into the compact node and then reaches the His bundle and propagates down the left and right bundle branches. Transmembrane action potentials recorded from in situ cardiomyocytes at various locations within the nodal tract exhibit distinct shapes and time courses (see Fig. 33-7D). Action potentials from extranodal atrial tissue and the His bundle (locations 1 and 5, respectively, in Fig. 33-7C) have more hyperpolarized diastolic potentials and faster upstrokes than do myocytes in the transitional zone (location 3) and penetrating bundle (location 4). This smaller rate of depolarization results in slowing of conduction across the compact portion and penetrating bundle (conduction velocity, <10 cm/sec versus 35 cm/sec in atrial working myocardium), thereby giving rise to the AV conduction delay.

**VIDEO 33-1**

Simulation of anterograde conduction through the atrioventricular node (AVN) using an electroanatomical model. The preparation is stimulated at the interatrial septum as shown by the stimulating electrodes. There is a flash and click coincident with the stimulus. (From Li J, Greener ID, Inada S, et al: Computer three dimensional reconstruction of the atrioventricular node. *Circ Res* 102:975, 2008.)

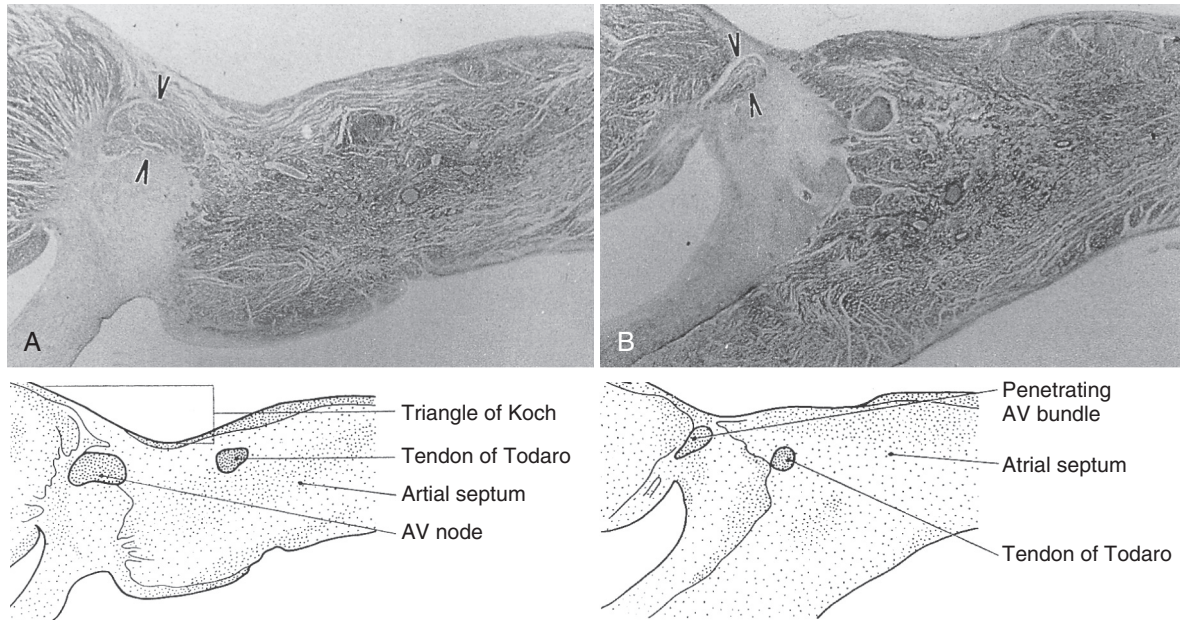

FIGURE 33-6 Sections through the AV junction show the position of the AV node (arrowheads) within the triangle of Koch (A) and the penetrating AV bundle of His (arrowheads) within the central fibrous body (B).

Bundle of His (Penetrating Portion of the Atrioventricular Bundle)

This structure is the continuation of the penetrating bundle on the ventricular side of the AV junction before it divides to form the left and right bundles (see Fig. 33-6A). Myocytes in the His bundle are small and connexin 43 positive (see Fig. 33-7C). However, large, well-formed fasciculoventricular connections between the penetrating portion of the AV bundle and the ventricular septal crest are rarely found in adult hearts. Branches from the anterior and posterior descending coronary arteries supply the upper muscular interventricular septum with blood, which makes the conduction system at this site more impervious to ischemic damage unless the ischemia is extensive.

Bundle Branches (Branching Portion of the Atrioventricular Bundle)

These structures begin at the superior margin of the muscular interventricular septum, immediately beneath the membranous septum, with cells of the left bundle branch cascading downward as a continuous sheet onto the septum beneath the noncoronary aortic cusp (Fig. 33-8A). The AV bundle may then give off other left bundle branches, sometimes constituting a true bifascicular system with an anterosuperior branch, in other hearts giving rise to a group of central fibers, and in still others appearing more as a network without clear division into a fascicular system (Fig. 33-8B). The right bundle branch continues intramyocardially as an unbranched extension of the AV bundle down the right side of the interventricular septum to the apex of the right ventricle and base of the anterior papillary muscle. In some human hearts, the His bundle traverses the right interventricular crest and gives rise to a right-sided narrow stem origin of the left bundle branch. The anatomy of the left bundle branch system can be variable and not conform to a constant bifascicular division. However, the concept of a trifascicular system remains useful to both electrocardiographers and clinicians (see Chapter 12).

Terminal Purkinje Fibers

These fibers connect with the ends of the bundle branches to form interweaving networks on the endocardial surface of both ventricles and transmit the cardiac impulse almost simultaneously to the entire right and left ventricular endocardium. Purkinje fibers tend to be less concentrated at the base of the ventricle and at the papillary

muscle tips. They penetrate the myocardium for varying distances, depending on the animal species. In humans, they apparently penetrate only the inner third of the endocardium, whereas in pigs, they almost reach the epicardium. Such variations could influence changes produced by myocardial ischemia, for example, because Purkinje fibers appear to be more resistant to ischemia than ordinary myocardial fibers are. Purkinje myocytes are found in the His bundle and bundle branches, cover much of the endocardium of both ventricles (see Fig. 33-8B), and align to form multicellular bundles in longitudinal strands separated by collagen. Although conduction of cardiac impulses appears to be their major function, free-running Purkinje fibers composed of many Purkinje cells in a series, sometimes called false tendons, are capable of contraction. Action potentials propagate within the thin Purkinje fiber bundles from the base to the apex before activation of the surrounding myocytes occurs. Purkinje myocytes largely lack transverse tubules (Fig. e33-1), which reduces membrane capacitance and thus accelerates action potential propagation.¹² Propagation of action potentials within the His-Purkinje system and working myocardium is mediated by connexins. Ventricular myocytes express mainly connexin 43, and Purkinje fibers express connexins 40 and 45. The molecular identity of the connexin type that enables transmission of impulses at the Purkinje fiber–myocyte junction (PMJ) is unclear. It is also still not clear how the small amount of depolarizing current provided by the thin bundle of Purkinje fibers can activate a much larger mass of ventricular muscle (current-to-load mismatch).¹³ It is possible that individual gap junctional channels at the PMJ are formed by more than one connexin isoform. These disparate connexin phenotypes may create specific types of hybrid channels with unique properties that ensure safe conduction at the PMJ. Because Purkinje cells have markedly longer repolarization times than surrounding myocytes do (see Fig. 33-17E), these connexin hybrids could also decrease entrainment of repolarization at the PMJ and thereby increase repolarization gradients.

Innervation of the Atrioventricular Node, His Bundle, and Ventricular Myocardium

Pathways of Innervation. The AV node and His bundle region are innervated by a rich supply of cholinergic and adrenergic fibers with densities exceeding those found in the ventricular myocardium.¹⁴

FIGURE e33-1 Confocal fluorescence images of a Purkinje cell (**A**) and left ventricular cardiomyocyte (**B**) isolated from a rabbit heart. The cells were stained with the membrane-selective fluorescent dye di-8-ANEPPS to visualize the sarcolemma. Ventricular myocytes typically exhibit regularly spaced lines of increased dye fluorescence intensity that run perpendicular to the outer membrane. These lines correspond to invaginations of the outer membrane, so-called *transverse tubuli*. Purkinje myocytes lack transverse tubuli. (From Cordeiro JM, Spitzer KW, Giles WR, et al: Location of the initiation site of calcium transients and sparks in rabbit heart Purkinje cells. *J Physiol* 531:301, 2001.)

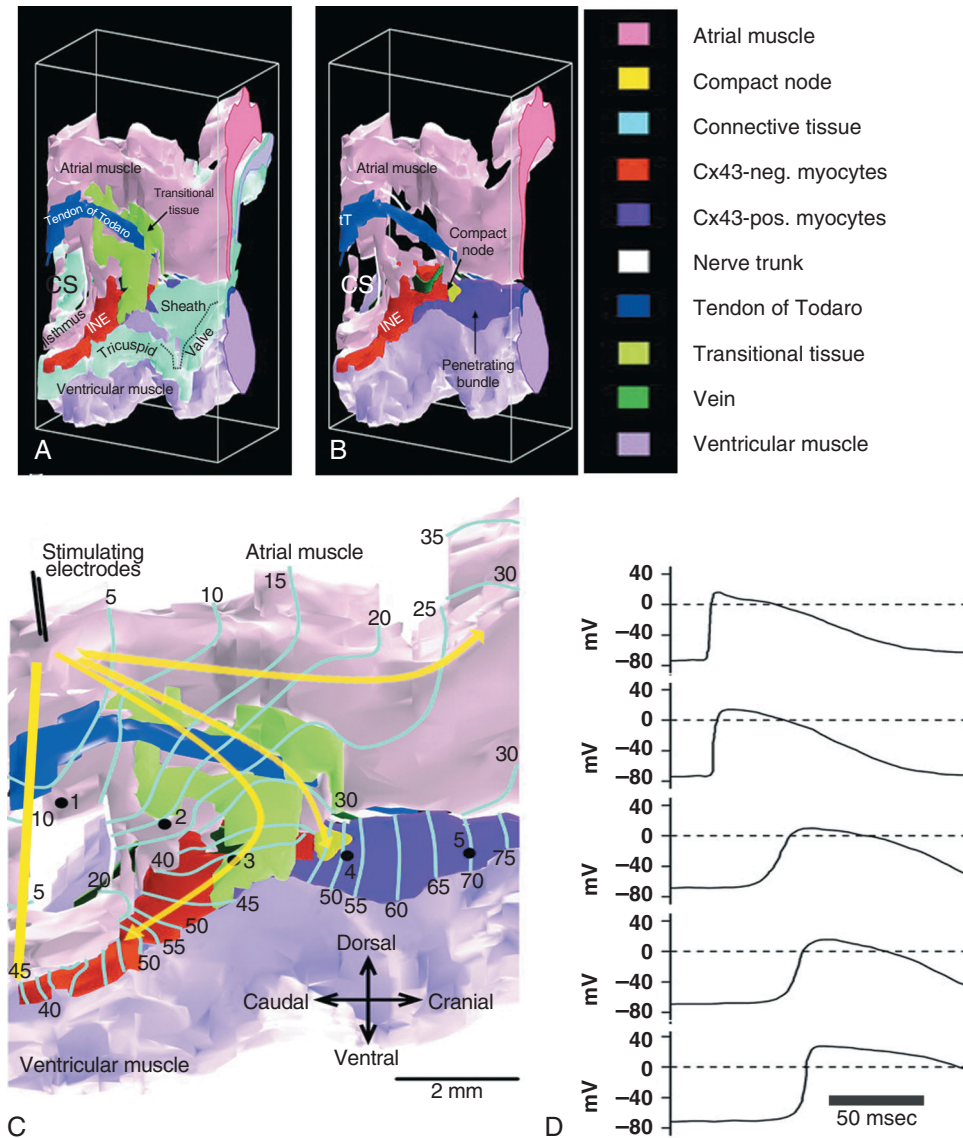

FIGURE 33-7 A, B, Computer-generated three-dimensional anatomic model of the AV node as viewed from the right atrium-ventricle. **A** shows all cell types. **B** shows the model after removal of transitional and connective tissue. The inferior nodal extension (INE) is located between the coronary sinus (CS) and the tricuspid valve, the end of the INE is covered by transitional tissue, the penetrating bundle begins at the apex of the triangle of Koch (formed by the CS, tendon of Todaro [TT], and tricuspid valve), and the penetrating bundle and His bundle are covered by connective tissue ("sheath"). After removal of the transitional and connective tissue, one sees protrusion of a connexin 43 (Cx43)-positive portion of nodal tissue into the Cx43-negative INE. The compact node is located at the junction of Cx43-negative and Cx43-positive nodal tissue. **C, D,** Structure-function relationships of the AV node. **C,** Schematic representation of the sequence of anterograde AV conduction by using a combination of mathematical modeling and experimental mapping of action potential propagation. The preparation is electrically stimulated at the crista terminalis. The activation sequence is shown as isochrones at 5-millisecond intervals. Yellow arrows delineate the conduction pathways. (See also Video 33-1.) **D,** Transmembrane action potentials recorded at locations demarcated by black dots in C (numbered 1 through 5). (Modified from Li J, Greener ID, Inada S, et al: Computer three dimensional reconstruction of the atrioventricular node. *Circ Res* 102:975, 2008. By permission of the American Heart Association.)

Immunolabeling with markers for sympathetic and parasympathetic nerves revealed nonuniform innervation density in the AV junctional area. For example, the inferior nodal extension has been shown to exhibit a higher density of both nerve types than the working atrial myocardium does, whereas the opposite is true for the compact node.¹⁵ Ganglia, nerve fibers, and nerve nets lie close to the AV node. Parasympathetic nerves to the AV node region enter the canine heart at the junction of the inferior vena cava and the inferior aspect of the left atrium, adjacent to the entrance to the coronary sinus. Nerves in direct contact with AV nodal fibers have been noted, along with agranular and granular vesicular processes, which presumably represent cholinergic and adrenergic processes.

In general, autonomic neural input to the heart exhibits some degree of "sidedness," with the right sympathetic and vagal nerves

affecting the sinoatrial node more than the AV node and the left sympathetic and vagal nerves affecting the AV node more than the sinoatrial node. The distribution of neural input to the sinoatrial and AV nodes is complex because of substantial overlapping innervation. Despite the overlap, specific branches of the vagal and sympathetic nerves can be shown to innervate certain regions preferentially. Supersensitivity to acetylcholine follows vagal denervation. Stimulation of the right stellate ganglion produces sinus tachycardia with less effect on AV nodal conduction, whereas stimulation of the left stellate ganglion generally produces a shift in the sinus pacemaker to an ectopic site and consistently shortens AV nodal conduction time and refractoriness but inconsistently speeds the sinoatrial nodal discharge rate. Stimulation of the right cervical vagus nerve primarily slows the sinoatrial nodal discharge rate, and stimulation of the left vagus primarily prolongs AV nodal conduction time and refractoriness when sidedness is present. Neither sympathetic nor vagal stimulation affects normal conduction in the His bundle. The negative dromotropic response of the heart to vagal stimulation is mediated by the activation of $I_{K, Ach, Ader}$, which results in hyperpolarization of the AV nodal cells and thereby influences the conductive properties of the node. The positive dromotropic effect of sympathetic stimulation arises as a consequence of an increase in cytosolic cAMP levels and ensuing activation of the L-type Ca^{2+} current $I_{Ca,L}$ (see Table 33-3).

Most efferent sympathetic impulses reach the canine ventricles over the ansae subclaviae, branches from the stellate ganglia. Sympathetic nerves then synapse primarily in the caudal cervical ganglia and form individual cardiac nerves that innervate relatively localized parts of the ventricles. The major route to the heart is the recurrent cardiac nerve on the right side and the ventrolateral cardiac nerve on the left. In general, the right sympathetic chain shortens refractoriness primarily of the anterior portion of the ventricles, and the left affects primarily the posterior surface of the ventricles, although overlapping areas of distribution occur.

The intraventricular route of sympathetic nerves generally follows the coronary arteries. Functional data

have suggested that afferent and efferent sympathetic nerves travel in the superficial layers of the epicardium and dive to innervate the endocardium, and anatomic observations have supported this conclusion. Vagal fibers travel intramurally or subendocardially and rise to the epicardium at the AV groove (Fig. 33-9A). Sympathetic nerve density in the left ventricle appears to be higher in the epicardial than in the endocardial portion of the ventricle, which at least in part results from transmural gradients in the expression of cytokines during cardiac development that attract and repel, respectively, sympathetic nerve growth (Fig. 33-9B).^{14,16}

Effects of Vagal Stimulation. The vagus modulates cardiac sympathetic activity at prejunctional and postjunctional sites by regulating the amount of norepinephrine released and by inhibiting cAMP-induced phosphorylation of cardiac proteins, including ion channels

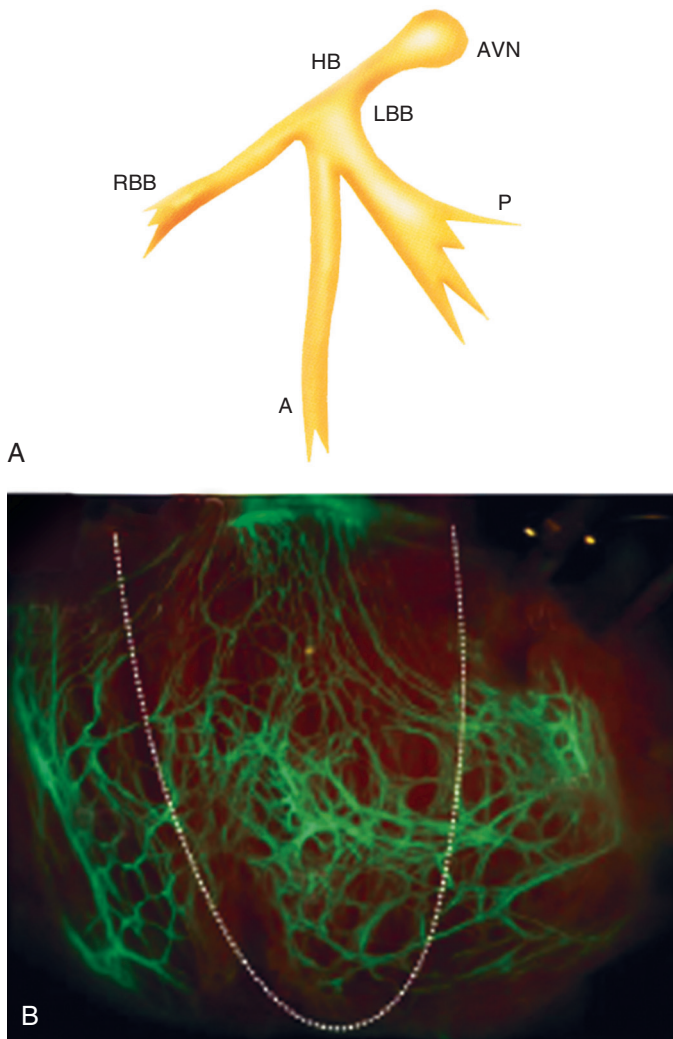

FIGURE 33-8 **A**, Schematic representation of the trifascicular bundle branch system. **B**, Structural organization of the His-Purkinje system in the mouse heart. Expression of a green fluorescent protein was specifically targeted to cells of the His-Purkinje system in mice. Green fluorescent cell networks in the left ventricular chamber are shown. The left ventricular free wall (LVFW) was incised from the base to the apex, and then the two parts of the LVFW were pulled back to expose the left flank of the interventricular septum (LF). The dotted line demarcates the border between the LF and the LVFW. A = anterosuperior fascicle of the left bundle branch; AVN = atrioventricular node; HB = His bundle; LBB = left bundle branch; P = posteroinferior fascicle of the left bundle branch; RBB = right bundle branch. (**A**, Modified from Rosenbaum MB, Elizari MV, Lazzari JO: *The Hemiblocks*. Oldsmar, Fla, Tampa Tracings, 1970, cover illustration; **B**, from Micquero L, Meysen S, Mangoni M, et al: *Architectural and functional asymmetry of the His-Purkinje system of the murine heart*. *Cardiovasc Res* 63:77, 2004.)

and calcium pumps. The latter inhibition occurs at more than one level in the series of reactions constituting the adenylate cyclase-, cAMP-dependent protein kinase system. Neuropeptides released from the nerve fibers of both autonomic limbs also modulate autonomic responses. For example, NPY released from sympathetic nerve terminals inhibits cardiac vagal effects.

Tonic vagal stimulation produces a greater absolute reduction in the sinoatrial rate in the presence of tonic background sympathetic stimulation, a sympathetic-parasympathetic interaction termed *accentuated antagonism*. In contrast, changes in AV conduction during concomitant sympathetic and vagal stimulation are essentially the algebraic sum of the individual AV conduction responses to tonic vagal and sympathetic stimulation alone. Cardiac responses to brief vagal bursts begin after a short latency and dissipate quickly; in contrast, cardiac responses to sympathetic stimulation commence and dissipate slowly. The rapid onset and offset of responses to vagal stimulation allow dynamic beat-to-beat vagal modulation of the heart rate and AV conduction, whereas the slow temporal response to sympathetic

stimulation precludes any beat-to-beat regulation by sympathetic activity. Periodic vagal bursting, as may occur each time that a systolic pressure wave arrives at the baroreceptor regions in the aortic and carotid sinuses, induces phasic changes in sinus cycle length and can entrain the sinus node to discharge faster or slower at periods identical to those of the vagal burst. In a similar phasic manner, vagal bursts prolong AV nodal conduction time and are influenced by background levels of sympathetic tone. Because the peak vagal effects on sinus rate and AV nodal conduction occur at different times in the cardiac cycle, a brief vagal burst can slow the sinus rate without affecting AV nodal conduction or can prolong AV nodal conduction time and not slow the sinus rate. Bilateral but not unilateral vagal nerve stimulation increases and reverses the spatial dispersion of ventricular repolarization as the direction of repolarization from the apex to the base in sinus rhythm shifts from the base to the apex. This effect is attributable to more pronounced prolongation of the action potential at the apex than at the base of the heart (Fig. e33-2).¹⁷

Effects of Sympathetic Stimulation. Similar to bilateral vagal nerve stimulation, sympathetic nerve stimulation also increases and reverses the spatial gradients of ventricular repolarization as the direction of polarization from the apex to the base in sinus rhythm shifts from the base to the apex. This reversal results from a marked shortening of action potential duration at the base, with no or very little effect on the repolarization time course at the apex of the heart (see Fig. e33-2).¹⁷ Nonuniform distribution of sympathetic nerves—and thus norepinephrine levels—may in part contribute to some of the nonuniform electrophysiologic effects because the ventricular content of norepinephrine is greater at the base than at the apex of the heart.¹¹ In humans, both direct and reflex sympathetic stimulation increases regional differences in cardiac repolarization. The dispersion of repolarization is significantly enhanced in patients with ischemic cardiomyopathy.¹⁸ Afferent vagal activity appears to be higher in the posterior ventricular myocardium, which may account for the vagomimetic effects of inferior myocardial infarction.

The vagi exert minimal but measurable effects on ventricular tissue; they decrease the strength of myocardial contraction and prolong refractoriness. Under some circumstances, acetylcholine can cause a positive inotropic effect. It is now clear that the vagus (acetylcholine) can exert direct effects on some types of ventricular fibers, as well as indirect effects by modulating sympathetic influences.

Beyond the beat-to-beat regulation of rate and contractile force, sympathetic input to the heart, through both translational and post-translational modifications, also exerts long-term regulation of adrenergic receptor sensitivity and ionic channels. These long-term changes in autonomic responsiveness and cardiac electrical properties appear to be mediated, at least in part, by highly localized signaling cascades involving neurally released molecules such as NPY.¹⁹

Arrhythmias and the Autonomic Nervous System

Alterations in vagal and sympathetic innervation (autonomic remodeling) can influence the development of arrhythmias and result in sudden cardiac death from ventricular tachyarrhythmias.²⁰ Damage to nerves extrinsic to the heart, such as the stellate ganglia, and to intrinsic cardiac nerves from diseases that may affect primarily nerves, such as viral infections, or from diseases that secondarily cause cardiac damage may produce cardioneuropathy. Although the mechanisms by which altered sympathetic innervation modulates cardiac electrical properties are largely unknown, spatially heterogeneous sympathetic hyperinnervation could result in enhanced dispersion of myocardial excitability and refractoriness via patchy adrenergic stimulation of ionic currents, including $I_{Ca,L}$, I_{Ks} , and I_{Cl} (see Table 33-3). Sympathetic hypoinnervation has been shown to increase the sensitivity of adrenergic receptors to activation by circulating catecholamines (denervation supersensitivity).¹⁴

Numerous studies have suggested a primary role of altered cardiac sympathetic innervation in arrhythmogenesis. Chronic infusion of nerve growth factor into the left stellate ganglion in dogs with chronic myocardial infarction and complete AV block caused spatially heterogeneous sympathetic cardiac hyperinnervation (nerve sprouting) and dramatically increased the incidence of sudden death from ventricular tachyarrhythmias.²⁰ Ambulatory long-term recordings of left stellate ganglion nerve activity in these dogs revealed that most malignant ventricular arrhythmias were preceded by increased neuronal discharge,

FIGURE e33-2 Reversal of the ventricular repolarization sequence during autonomic nerve stimulation in a rabbit heart. Each map represents the dispersion of repolarization for a single cardiac beat and is displayed as an isochronal map with lines 2 milliseconds apart. Light to dark shades represent early to late repolarization time points. Arrows point to the direction of the repolarization sequence. CTRL = control; SNS = sympathetic nerve stimulation; VNSBL = bilateral vagal nerve stimulation; VNSL = left vagal nerve stimulation; VNSR = right vagal nerve stimulation. (From Mantravadi R, Gabris B, Liu T, et al: Autonomic nerve stimulation reverses ventricular repolarization sequence in rabbit hearts. *Circ Res* 100:e72, 2007. With permission from the American Heart Association.)

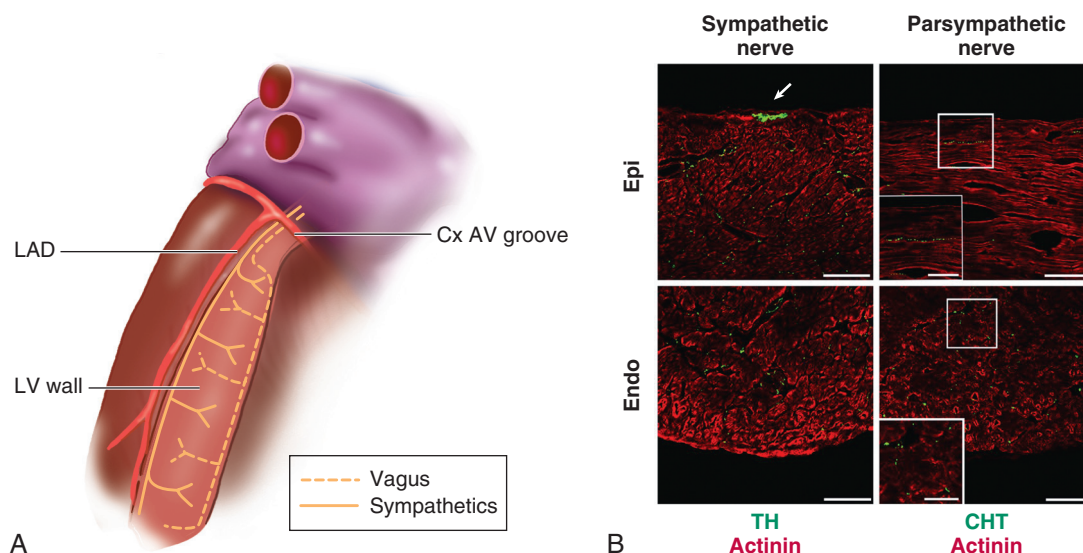

FIGURE 33-9 **A**, Intraventricular route of the sympathetic and vagal nerves to the left ventricle (LV). LAD = left anterior descending artery. **B**, Distribution of sympathetic and parasympathetic nerves in the mammalian heart. Immunofluorescence staining for the sympathetic and parasympathetic nerve markers tyrosine hydroxylase (TH) and choline transporter (CHT) is shown in the left ventricle of a rat heart (green: nerves; red: alpha-actinin, a cardiomyocyte marker). TH-positive nerves are more abundant in the subepicardial (epi) layer than in the subendocardial (endo) layer. The arrow indicates sympathetic nerves at the epicardial surface. No CHT-positive nerves are present at the epicardial surface, and CHT-positive nerves are more abundant in the subendocardial layer. Higher magnification views of the boxed regions are shown in the insets. Scale bars = 100 μm. (**A**, From Ito M, Zipes DP: Efferent sympathetic and vagal innervation of the canine right ventricle. *Circulation* 90:1459, 1994. By permission of the American Heart Association; **B**, from Kanazawa H, Ieda M, Kimura K, et al: Heart failure causes cholinergic transdifferentiation of cardiac sympathetic nerves via gp130-signaling cytokines in rodents. *J Clin Invest* 120:408, 2010.)

FIGURE 33-10 Sympathetic neural remodeling in diseased heart. **A**, Regional hyperinnervation (arrowhead) at the junction between necrotic and normal, surviving myocardium (M) in a patient with cardiomyopathy and ventricular tachyarrhythmias. **B**, Cholinergic transdifferentiation of cardiac sympathetic nerves in failing human hearts. Shown are representative cross sections of epicardial nerve bundles in the left ventricle of a nonfailing (upper row) and a failing human heart. Hearts were stained for tyrosine hydroxylase (TH; red) and choline transporter (CHT; green) as catecholaminergic and cholinergic nerve markers, respectively. The failing heart exhibits fewer TH-positive nerves and markedly more CHT-positive nerves than does the nonfailing heart, whereas overall nerve density appears to be similar. The right panels display merged images of the TH and CHT signal, which reveals that in the failing heart some nerves coexpress TH and CHT (yellow color because of the overlap of red TH and green CHT fluorescence). Higher magnification views of the boxed regions are shown in the insets. The arrowhead in the lower left corner of the far right image denotes a nerve coexpressing TH and CHT. Scale bar, 10 μm; insets, 50 μm. (**A**, From Cao J, Fishbein MC, Han JB, et al: Relationship between regional cardiac hyperinnervation and ventricular arrhythmia. *Circulation* 101:1960, 2000. By permission of the American Heart Association; **B**, from Kanazawa H, Ieda M, Kimura K, et al: Heart failure causes cholinergic transdifferentiation of cardiac sympathetic nerves via gp130-signaling cytokines in rodents. *J Clin Invest* 120:408, 2010.)

thus suggesting a causal role of sympathetic input in triggering arrhythmogenic sudden cardiac death.²¹ A high-cholesterol diet was reported to result in cardiac sympathetic hyperinnervation in rabbits and a marked increase in the incidence of ventricular fibrillation (VF).²² Explanted human hearts from transplant recipients with a history of arrhythmias exhibited a significantly higher and also more heterogeneous density of sympathetic nerve fibers than did those from patients without arrhythmias (Fig. 33-10A). Whether neural remodeling also involved parasympathetic nerve fibers in the heart was not examined in these studies. In patients with congestive heart failure, sympathetic neural tone is upregulated, and excess activation of the sympathetic nervous system leads to adverse myocardial effects, including lethal arrhythmias, and also causes depletion of cardiac norepinephrine content. This depletion of norepinephrine has recently been shown to result, at least partially, from neurotransmitter switching and

transdifferentiation from catecholaminergic into cholinergic neurons in the chronically failing heart (Fig. 33-10B).²³ This process is induced by release of cholinergic differentiation factors from failing cardiomyocytes. It remains to be determined, however, whether neurotransmitter switching is an adaptive response to protect the heart from excess sympathetic stimulation and thus lethal arrhythmias. Interestingly, beta adrenoceptor blockade in rats with coronary artery ligation reversed the myocardial sympathetic axon depletion in intact myocardium remote from the infarct but did not affect peri-infarct sympathetic hyperinnervation.²⁴ The junctions between pulmonary veins and the left atrium are highly innervated structures. Both sympathetic and parasympathetic nerves are collocated and concentrated in "ganglionated plexuses" around the pulmonary veins.²⁵ Selective ablation of ganglionated plexuses, as well as extensive regional ablation targeting anatomic areas containing ganglionated plexuses, has been shown to

reduce the incidence of paroxysmal atrial fibrillation (AF) in both clinical and experimental studies, thus further supporting a causal involvement of autonomic nerve activity in atrial arrhythmogenesis.^{26,27} On the other hand, spatially heterogeneous sympathetic denervation was similarly associated with an increased risk for atrial and ventricular arrhythmias. Mutations in genes encoding cardiac ion channel subunits also affect channel function in the central and peripheral autonomic nervous system and thereby result in abnormal firing properties of affected neurons.^{28,29} This observation may partially explain the clinical finding that sudden cardiac death in some variants of long-QT syndrome (LQTS; see Chapters 32, 34, and 37) is typically preceded by sympathetic arousal. Also, the antiarrhythmic efficacy of surgical left cardiac sympathetic denervation has previously been demonstrated in young patients with catecholaminergic polymorphic ventricular tachycardia (CPVT), an inherited arrhythmia caused by missense mutations in the gene encoding the cardiac ryanodine receptor Ca^{2+} release channel.³⁰ Thus the cardiac sympathetic nervous system provides a potentially useful target for treating patients at risk for clinical arrhythmias.³¹

BASIC ELECTROPHYSIOLOGIC PRINCIPLES

Physiology of Ion Channels

Electrical signaling in the heart involves the passage of ions through ionic channels. The Na^+ , K^+ , Ca^{2+} , and Cl^- ions are the major charge carriers, and their movement across the cell membrane creates a flow of current that generates excitation and signals in cardiac myocytes. Ion channels are macromolecular pores that span the lipid bilayer of the cell membrane (Fig. 33-11). Conformational transitions change (gate) a single ion channel from closed to open, which allows selected ions to flow passively down the electrochemical activity gradient at a very high rate (>10⁶ ions per second). The high transfer rates and restriction to “downhill” fluxes not stoichiometrically coupled to the hydrolysis of energy-rich phosphates distinguish ionic channel mechanisms from those of other ion-transporting structures, such as sarcolemmal Na^+ , K^+ -adenosine triphosphatase (ATPase) or sarcoplasmic reticular Mg^{2+} , Ca^{2+} -ATPase (SERCA). Ion channels may be gated by extracellular and intracellular ligands, changes in transmembrane voltage, or mechanical stress (see Table 33-3). Gating of single ion channels can best be studied by means of the patch-clamp technique.

FIGURE 33-11 Structure of ion channels. Voltage-gated Na^+ and Ca^{2+} channels are composed of a single tetramer consisting of four covalently linked repeats of the six transmembrane-spanning motifs, whereas voltage-gated K^+ channels are composed of four separate subunits, each containing a single six transmembrane-spanning motif. Inwardly rectifying K^+ channels are formed by inward rectifier K^+ channel pore-forming (alpha) subunits. In contrast to voltage-gated K^+ channel alpha subunits, the Kir alpha subunits have only two (not six) transmembrane domains. (Modified from Katz AM: *Molecular biology in cardiology, a paradigmatic shift*. *J Mol Cell Cardiol* 20:355, 1988; and Shivkumar K, Weiss JN: Adenosine triphosphate-sensitive potassium channels. In Zipes DP, Jalife J [eds]: *Cardiac Electrophysiology: From Cell to Bedside*. Philadelphia, WB Saunders, 1999, pp 86-93.)

Ion channels are usually named after the strongest permeant ion— Na^+ , K^+ , Ca^{2+} , and Cl^- —but some channels are less selective or are not selective, as in gap junctional channels. Channels have also been named after neurotransmitters, as in acetylcholine-sensitive K^+ channels, $\text{I}_{\text{K,ACh}}$.

The ionic permeability ratio is a commonly used quantitative index of a channel's selectivity. It is defined as the ratio of the permeability of one ion type to that of the main permeant ion type. Permeability ratios of voltage-gated K^+ and Na^+ channels for monovalent and divalent (e.g., Ca^{2+}) cations are usually less than 1:10. Voltage-gated Ca^{2+} channels exhibit a more than 1000-fold discrimination against Na^+ and K^+ ions (e.g., $P_{\text{K}}/P_{\text{Ca}} = 1/3000$) and are impermeable to anions.

Because ions are charged, net ionic flux through an open channel is determined by both the concentration and electrical gradient across the membrane (electrodiffusion). The potential at which the passive flux of ions along the chemical driving force is exactly balanced by the electrical driving force is called the reversal or Nernst potential of the channel. In the case of a channel that is perfectly selective for one ion species, the reversal potential equals the thermodynamic equilibrium potential of that ion, E_s , which is given by the Nernst equation in the form

$$E_s = (RT/zF) \ln([S_o]/[S_i])$$

where $[S_i]$ and $[S_o]$ are the intracellular and extracellular concentrations of the permeant ion, respectively, z is the valence of the ion, R is the gas constant, F is the Faraday constant, T is the temperature (kelvin), and \ln is the logarithm to the base e . At membrane voltages more positive than the reversal potential of the channel, passive ion movement is outward, whereas it is inward at membrane potentials more negative than the Nernst potential of that channel. If the current through an open channel is carried by more than one permeant ion, the reversal potential becomes a weighted mean of all Nernst potentials.

Membrane voltages during a cardiac action potential are in the range of -94 to $+30$ mV (Table 33-1). With physiologic external K^+ (4 mM), E_K is approximately -91 mV, and passive movement of K^+ during an action potential is out of the cell. On the other hand, because the calculated reversal potential of a cardiac Ca^{2+} channel is $+64$ mV (assuming that $P_{\text{K}}/P_{\text{Ca}} = 1/3000$, $K_i = 150$ mM, $K_o = 4$ mM, $\text{Ca}_i = 100$ nM, and $\text{Ca}_o = 2$ mM), passive Ca^{2+} flux is into the cell. With physiologic internal and external chloride concentrations, E_{Cl} is -83 to -36 mV, and passive movement of Cl^- ions through open chloride channels can be both inward and outward at membrane potentials typically occurring during a cardiac action potential. In more general terms, the direction and magnitude of passive ion flux through a single open channel at any given transmembrane voltage are governed by the reversal potential of that ion and its concentration on the two sides of the membrane, with the net flux being larger when ions move from the more concentrated side.

Ion Flux Through Voltage-Gated Channels. Changes in transmembrane potential determine ion flux through voltage-gated channels, not only through the voltage dependence of the electrochemical driving force on the permeant ion but also through the voltage dependence of channel activation; that is, the fraction of time that a channel permits ions to permeate is determined by the membrane voltage. If the probability of a channel being activated (i.e., the open-state probability of that channel) exhibits voltage dependence, as is the case with the fast Na^+ channel or voltage-dependent K^+ channels in cardiac myocytes, activation increases with membrane depolarization. Note that channels do not have a sharp voltage threshold for opening. Rather, dependence of channel activation on membrane potential is a continuous function of voltage and follows a sigmoidal curve (Fig. 33-12, blue curve). The potential at which activation is half-maximal and the steepness of the activation curve determine the channel's activity during changes in membrane potential. Shifting the activation curve to potentials positive to the midpoint of activation and reducing the steepness of the channel's activation curve are two possible mechanisms by which ion channel blockers can inhibit ion channel activity.

As indicated in Figure 33-13, open channels enter a nonconducting conformation after a depolarizing change in membrane potential, a process termed *inactivation*. If membrane depolarization persists, the channel remains inactivated and cannot reopen. This steady-state inactivation increases with membrane depolarization in a sigmoidal fashion (see Fig. 33-12, gold curve). Inactivation curves of the various voltage-gated ion channel types in the heart differ in their slopes and

TABLE 33-1 Intracellular and Extracellular Ion Concentrations in Cardiac Muscle

ION	EXTRACELLULAR CONCENTRATION	INTRACELLULAR CONCENTRATION	RATIO OF EXTRACELLULAR TO INTRACELLULAR CONCENTRATION	E _i (mV)
Na ⁺	145 mM	15 mM	9.7	+60
K ⁺	4 mM	150 mM	0.027	−94
Cl [−]	120 mM	5–30 mM	4–24	−83 to −36
Ca ²⁺	2 mM	10 ^{−7} M	2 × 10 ⁴	+129

Although intracellular Ca²⁺ content is about 2 mM, most of this Ca²⁺ is bound or sequestered in intracellular organelles (mitochondria and sarcoplasmic reticulum). E_i = equilibrium potential for a particular ion at 37°C.
 Modified from Sperelakis N: *Origin of the cardiac resting potential*. In Berne RM, Sperelakis N, Geiger SR (eds): *Handbook of Physiology: The Cardiovascular System*. Bethesda, Md, American Physiological Society, 1979, p 193.

FIGURE 33-12 Voltage dependence of fast Na⁺ current steady-state activation (blue) and steady-state inactivation (gold). Fractional activation and inactivation (y axis) are plotted as a function of membrane potential. The inactivation and activation curves overlap within a voltage range from approximately −60 to approximately 0 mV, which demarcates the voltage range of the noninactivating Na⁺ window current.

midpoints of inactivation. For example, sustained cardiomyocyte membrane depolarization to −50 mV (as may occur in acutely ischemic myocardium) causes almost complete inactivation of the fast voltage-gated Na⁺ channel (see Fig. 33-12, gold curve), whereas the L-type Ca²⁺ channel exhibits only little inactivation at this membrane potential. Activation and inactivation curves can overlap, in which case a steady-state or noninactivating current flows. The existence of such a “window” current has been verified for both the voltage-gated Na⁺ current³² and the L-type Ca²⁺ current. The L-type Ca²⁺ current and the fast Na⁺ window current have been implicated in the genesis of triggered activity arising from early afterdepolarization (EAD) and delayed afterdepolarization (DAD).³³

Channels recover from inactivation and then enter the closed state, from which they can be reactivated (see Fig. 33-13). Rates of recovery from inactivation vary among the different types of voltage-dependent channels and usually follow monoexponential or multiexponential time courses, with the longest time constants ranging from a few milliseconds, for example, as for the fast sodium channel, to several seconds, as for some subtypes of K⁺ channels (see Table 33-3). Together, the activity of voltage-dependent ion channels in cardiomyocytes over the course of an action potential is tightly regulated by the orchestrated interplay of a number of time- and voltage-dependent gating mechanisms, including activation, inactivation, and recovery from inactivation. All these mechanisms represent potential targets for pharmacologic intervention.

Principles of Ionic Current Modulation. The whole-cell current amplitude *I* is the product of the number of functional channels in the membrane available for opening (*N*), the probability that a channel will open (*P_o*), and the single-channel current amplitude (*i*), or *I* = *N* • *P_o* • *i*. Modulation of current amplitudes in single cardiomyocytes therefore results from alterations in *N*, *P_o*, *i*, or any combination of these factors. Changes in the number of available channels in the cell

FIGURE 33-13 Simplest scheme for gating of voltage-gated ion channels.

membrane may result from alterations in the expression of ion channel–encoding genes. The magnitude of the single-channel current amplitude is dependent, among other factors, on the ionic concentration gradient across the membrane. For example, an increase in the extracellular Ca²⁺ concentration increases current through a single Ca²⁺ channel. Changes in channel activation can result from phosphorylation or dephosphorylation of the channel protein by second messenger–mediated activation of protein kinases and protein phosphatases, respectively. Channel phosphorylation or dephosphorylation causes a shift in the membrane potential dependence of a channel’s activation or availability curve, or both, or modification of the sensitivity of channel activation or inactivation to changes in membrane potential. For example, Ca²⁺/calmodulin kinase II–mediated phosphorylation shifts the activation curve of the cardiac sodium current to more negative potentials.³⁴

Molecular Structure of Ion Channels. Electrophysiologic studies have detailed the functional properties of Na⁺, Ca²⁺, and K⁺ currents in cardiomyocytes, and molecular cloning has revealed a large number of pore-forming (alpha) and auxiliary (beta, delta, and gamma) subunits thought to contribute to formation of the cell surface ion channels. These studies have demonstrated that distinct molecular entities give rise to the various cardiac ion channels and shape the myocardial action potential. It has also been demonstrated that mutations in the genes encoding subunits underlying functional cardiac ion channels are responsible for several inherited cardiac arrhythmias (see Chapter 32).³⁵ The expression and functional properties of myocardial ion channels also change in a number of acquired disease states, and these alterations can predispose to cardiac arrhythmias.^{36,37}

A more detailed description of the molecular composition of sodium, calcium, potassium, and pacemaker channels is provided online at ExpertConsult.

Intercalated Discs

Another family of ion channel proteins is that containing the gap junctional channels. These dodecameric channels are found in the intercalated discs between adjacent cells. Three types of specialized junctions make up each intercalated disc. The macula adherens or desmosome and the fascia adherens form areas of strong adhesion between cells and may provide a linkage for the transfer of mechanical energy from one cell to the next. The nexus, also called the tight or gap junction, is a region in the intercalated disc where cells are in functional contact with each other. Membranes at these junctions are separated by only about 10 to 20 Å and are connected by a series of hexagonally packed subunit bridges. Gap junctions provide biochemical and low-resistance electrical coupling between adjacent cells by

establishing aqueous pores that directly link the cytoplasm of these adjacent cells. Gap junctions allow the movement of ions (e.g., Na^+ , Cl^- , K^+ , Ca^{2+}) and small molecules (e.g., cAMP, cyclic guanosine monophosphate [cGMP], inositol 1,4,5-triphosphate [IP_3]) between cells, thereby linking the interiors of adjacent cells.

Gap junctions permit a multicellular structure such as the heart to function electrically like an orderly, synchronized, interconnected unit and are probably responsible in part for the fact that conduction in the myocardium is anisotropic; that is, its anatomic and biophysical properties vary according to the direction in which they are measured. Usually, conduction velocity is two to three times faster longitudinally, in the direction of the long axis of the fiber, than it is transversely, in the direction perpendicular to this long axis.³⁸ Resistivity is lower longitudinally than transversely. Interestingly, the safety factor for propagation is greater transversely than horizontally. The safety factor for conduction determines the success of action potential propagation and has been defined as the ratio of electrical charge that is generated to charge that is consumed during the excitation cycle of a single myocyte in tissue.³⁸ Conduction delay or block occurs more commonly in the longitudinal direction than it does transversely. Cardiac conduction is discontinuous because of resistive discontinuities created by the gap junctions, which have an anisotropic distribution on the cell surface.³⁸ Because of anisotropy, propagation is discontinuous and can be a cause of reentry.

Gap junctions also provide “biochemical coupling,” which permits cell-to-cell movement of ATP (or other high-energy phosphates), cyclic nucleotides, and IP_3 , the activator of the IP_3 -sensitive SR Ca^{2+} release channel,³⁹ thus demonstrating that diffusion of second-messenger substances through gap junctional channels constitutes a mechanism enabling coordinated responses of the myocardial syncytium to physiologic stimuli.

Gap junctions can also change their electrical resistance. When the intracellular calcium level rises, as in myocardial infarction, the gap junction may close to help seal off the effects of injured from noninjured cells. Acidosis increases and alkalosis decreases gap junctional resistance. Increased gap junctional resistance tends to slow the rate of action potential propagation, a condition that could lead to conduction delay or block. Cardiac-restricted inactivation of gap junctions decreases transverse conduction velocity to a greater degree than longitudinal conduction, thereby resulting in an increased anisotropic ratio, which may play a role in premature sudden death from ventricular arrhythmias.⁴⁰

Connexins are the proteins that form the intercellular channels of gap junctions. An individual channel is created by two hemichannels (connexons), each located in the plasma membrane of adjacent cells and composed of six integral membrane protein subunits (connexins). The hemichannels surround an aqueous pore and thereby create a transmembrane channel (Fig. 33-14). Connexin 43, a 43-kDa polypeptide, is the most abundant cardiac connexin, with connexins 40 and 45 being found in smaller amounts. Ventricular muscle expresses connexins 43 and 45, whereas atrial muscle and components of the specialized conduction system express connexins 43, 45, and 40. Expression of connexin 30.2 appears to be confined to the cardiac conduction system.⁴¹ Individual cardiac connexins form gap junctional channels with characteristic unitary conductances, voltage sensitivities, and permeabilities. Tissue-specific connexin expression and the spatial distribution of gap junctions determine the disparate conduction properties of cardiac tissue (see Fig. 33-7). The functional diversity of cardiac gap junctions is further enhanced by the ability of different connexin isoforms to form hybrid gap junctional channels with unique electrophysiologic properties. These channel chimeras appear to have a major function in controlling impulse transmission at the sinoatrial node-atrium border, the atrium-AV node transitional zone, and the Purkinje-myocyte border.⁵

Alterations in the distribution and function of cardiac gap junctions are associated with increased susceptibility to arrhythmias. Conduction slowing and arrhythmogenesis have been associated with redistribution of connexin 43 gap junctions from the end of cardiomyocytes to the lateral borders and with decreased phosphorylation of connexin 43 in a dog model of nonischemic dilated cardiomyopathy.^{42,43} Adult mice genetically engineered to express progressively decreasing levels of cardiac connexin 43 exhibited increased susceptibility to the induction of fatal tachyarrhythmias.^{44,45} Side-to-side electrical coupling between cardiomyocytes from the epicardial border zone of healing infarcts has been shown to be reduced, thereby exaggerating anisotropy and facilitating reentrant activity.⁴⁶ Finally, a rare single nucleotide polymorphism in the atrial-specific connexin 40 gene has been found to increase the risk for idiopathic AF.⁴⁷ Studies have suggested

FIGURE 33-14 Model of the structure of a gap junction based on the results of x-ray diffraction studies. Individual channels are composed of paired hexamers that travel in the membranes of adjacent cells and adjoin in the extracellular gap to form an aqueous pore that provides continuity of the cytoplasm of the two cells. A = angstroms. (From Saffitz JE: Cell-to-cell communication in the heart. *Cardiol Rev* 3:86, 1995.)

that normal electrical coupling of cardiomyocytes via gap junctions depends on normal mechanical coupling via cell-cell adhesion junctions.⁴⁸ A defect in cell-cell adhesion or a discontinuity in the linkage between intercellular junctions and the cytoskeleton prevents normal localization of connexins in gap junctions, which in turn could contribute to sudden death from tachyarrhythmias. For example, Carvajal syndrome is caused by a recessive mutation in desmoplakin, a protein that links desmosomal adhesion molecules to desmin, a filament protein of the cardiomyocyte cytoskeleton.⁴⁹ Naxos disease is caused by a recessive mutation in plakoglobin, a protein that connects N-cadherins to actin and desmosomal cadherins to desmin.⁵⁰ Approximately 70% of the mutations linked to familial arrhythmogenic right ventricular cardiomyopathy are in the gene encoding the desmosomal protein plakophilin 2. Recent experiments have demonstrated that loss of plakophilin 2 expression leads to redistribution of connexin 43 to the intracellular space of cardiomyocytes, loss of gap junction plaques, and reduced functional coupling between cells.⁵¹ Further demonstration of the important role of other adhesion proteins in stabilizing gap junctions comes from a study wherein conditional loss of N-cadherin expression in mouse hearts resulted in a decrease in connexin 43 gap junctions and changes in conduction velocity with a concomitant increase in arrhythmogenicity (Fig. e33-3).⁴⁰

Phases of the Cardiac Action Potential

The cardiac transmembrane action potential consists of five phases: phase 0, upstroke or rapid depolarization; phase 1, early rapid repolarization; phase 2, plateau; phase 3, final rapid repolarization; and phase 4, resting membrane potential and diastolic depolarization (Figs. 33-15 and 33-16). These phases are the result of passive ion fluxes moving down the electrochemical gradients established by active ion pumps and exchange mechanisms. Each ion moves primarily through its own ion-specific channel. The following discussion explains the electrogenesis of each of these phases.

General Considerations. Ionic fluxes regulate membrane potential in cardiac myocytes in the following fashion. When only one type of ion channel opens, assuming that this channel is perfectly selective for that ion, the membrane potential of the entire cell would equal the Nernst potential of that ion. By solving the Nernst equation for the four major ions across the plasma membrane, the following equilibrium potentials are obtained: sodium, +60 mV; potassium, −94 mV; calcium, +129 mV; and chloride, −83 to −36 mV (see Table 33-1). Therefore, if a single K^+ -selective channel opens, such as the inwardly rectifying K^+ channel, the membrane potential approaches E_K (−94 mV). If a single Na^+ -selective channel opens, the transmembrane potential becomes E_{Na} (+60 mV). A quiescent cardiac myocyte (phase 4) has many more open potassium than sodium channels, and the

FIGURE e33-3 Cardiac restricted loss of N-cadherin leads to alteration in connexin 43 (Cx43) with conduction slowing. **A-D**, Anti-N-cadherin (**A, C**) and anti-Cx43 (**B, D**) immunoreactivity in a control mouse heart (**A, B**) and in a genetically manipulated mouse heart with knocked-out N-cadherin expression (**C, D**). N-cadherin was lost from intercalated disc in the knocked-out heart, whereas Cx43 was significantly decreased. **E, F**, Optical mapping of electrical activation in the left ventricular epicardium of a control (**E**) and N-cadherin knocked-out heart (**F**) with a voltage-sensitive fluorescent dye. The heart was paced at the lateral wall and activation maps were generated. Color-coded isochrome maps show that conduction was more impaired in the longitudinal than in the lateral direction, thereby increasing conduction anisotropy. (From Li J, Patel VV, Kostetskii I, et al: Cardiac-specific loss of N-cadherin leads to alteration in connexins with conduction slowing and arrhythmogenesis. *Circ Res* 97:474, 2005. With permission from the American Heart Association.)

FIGURE 33-15 Demonstration of action potentials recorded during impalement of a cardiac cell. **Upper row.** Shown are a cell (circle), two microelectrodes, and stages during impalement of the cell and its activation and recovery. Both microelectrodes are extracellular (A), and no difference in potential exists between them (0 potential). The environment inside the cell is negative and the outside is positive because the cell is polarized. One microelectrode has pierced the cell membrane (B) to record the intracellular resting membrane potential, which is -90 mV with respect to the outside of the cell. The cell has depolarized (C), and the upstroke of the action potential is recorded. At its peak voltage, the inside of the cell is approximately $+30$ mV with respect to the outside of the cell. The repolarization phase (D) is shown, with the membrane returning to its former resting potential (E). (From Cranefield PF: *The Conduction of the Cardiac Impulse*. Mount Kisco, NY, Futura, 1975.)

FIGURE 33-16 Currents and channels involved in generating resting and action potentials. The time course of a stylized action potential of atrial and ventricular cells is shown on the **left**, and that of sinoatrial node cells is on the **right**. Above and below are the various channels and pumps that contribute the currents underlying the electrical events. See Table 33-3 for identification of the symbols and description of the channels or currents. Where possible, the approximate time courses of the currents associated with the channels or pumps are shown symbolically without trying to represent their magnitudes relative to each other. I_K incorporates at least two currents, I_{Kf} and I_{Ks} . There appears to be an ultrarapid component as well, designated I_{Kur} . The heavy bars for I_{CL} , I_{pump} , and I_{K-ATP} indicate only the presence of these channels or pump without implying magnitude of currents because the magnitude would vary with physiologic and pathophysiologic conditions. The channels identified by brackets (I_{NS} and I_{K-ATP}) are active only under pathologic conditions. I_{NS} may represent a swelling-activated cation current. For the sinoatrial node cells, I_{NS} and I_{K1} are small or absent. Question marks indicate that experimental evidence is not yet available to determine the presence of these channels in sinoatrial cell membranes. Although it is likely that other ionic current mechanisms exist, they are not shown here because their roles in electrogenesis are not sufficiently well defined. (From *Members of the Sicilian Gambit: Antiarrhythmic Therapy: A Pathophysiologic Approach*. Mount Kisco, NY, Futura, 1994, p 13.)

cell's transmembrane potential is close to E_K (Table 33-2). When two or more types of ion channels open simultaneously, each type tries to make the membrane potential go to the equilibrium potential of that channel. The contribution of each ion type to the overall membrane potential at any given moment is determined by the instantaneous permeability of the plasma membrane to that ion. For example, deviation of the measured resting membrane potential from E_K (see Table 33-1) would predict that other ion types with equilibrium potentials positive to E_K are contributing to the resting membrane potential in cardiac myocytes. If it is assumed that Na^+ , K^+ , and Cl^- are the

permeant ions at resting potential, their individual contributions to the resting membrane potential V can be quantified by the Goldman-Hodgkin-Katz voltage equation in the form

$$V = (RT/F) \ln[(P_K[Na]_o + P_{Cl}[Cl]_i)/P_K[K]_i + P_{Na}[Na]_o/P_{Cl}[Cl]_i]$$

where the symbols have the meanings outlined previously. With only one permeant ion, V becomes the Nernst potential for that ion. With several permeant ion types, V is a weighted mean of all the Nernst potentials.

Intracellular electrical activity can be recorded by inserting a glass microelectrode filled with an electrolyte solution and with a tip diameter smaller than $0.5 \mu m$ into a single cell. The electrode produces minimal damage, its entry point apparently being sealed by the cell. The transmembrane potential is recorded by using this electrode in reference to an extracellular ground electrode placed in the tissue bath near the cell membrane and represents the potential difference between intracellular and extracellular voltage (see Fig. 33-15). Alternatively, the patch-clamp technique in current clamp mode can be used to measure transmembrane potentials.

Phase 4: Resting Membrane Potential. The intracellular potential during electrical quiescence in diastole is -50 to -95 mV, depending on the type of cell (see Table 33-2). Therefore the inside of the cell is 50 to 95 mV negative relative to the outside of the cell because of the distribution of ions such as K^+ , Na^+ , and Cl^- .

Because cardiac myocytes have an abundance of open K^+ channels at rest, the cardiac transmembrane potential (in phase 4) is close to E_K . Potassium outward current through open, inwardly rectifying K^+ channels (I_{K1}) under normal conditions contributes to the resting membrane potential mainly in atrial and ventricular myocytes, as well as in Purkinje cells. Deviation of the resting membrane potential from E_K is the result of movement of monovalent ions with an equilibrium potential greater than the E_K , for example, Cl^- efflux through activated chloride channels, such as $I_{CL,CAMP}$, $I_{CL,Ca}$, and $I_{CL,swell}$. Calcium does not contribute directly to the resting membrane potential, but changes in intracellular free calcium concentration can affect other membrane conductance values. For example, an increase in sarcoplasmic reticulum (SR) Ca^{2+} load can cause spontaneous intracellular Ca^{2+} waves, which in turn activate the Ca^{2+} -dependent chloride conductance $I_{CL,Ca}$ and thereby lead to spontaneous transient inward currents and concomitant membrane depolarization.⁵² Increases in $[Ca^{2+}]_i$ can also stimulate the Na^+/Ca^{2+} exchanger $I_{Na/Ca}$. This protein exchanges three Na^+ ions for one Ca^{2+} ion; the direction is dependent on the sodium and calcium concentrations on the two sides of the membrane and the transmembrane potential difference. At resting membrane potential and during a spontaneous SR Ca^{2+} release event, this exchanger would generate a net Na^+ influx, possibly causing transient membrane depolarizations (see Fig. 33-20).⁵³ $[Ca^{2+}]_i$ has also been shown to activate I_{K1} in cardiac myocytes, thereby indirectly contributing to cardiac resting membrane potential. Because of the Na^+-K^+ pump, which pumps Na^+ out of the cell against its electrochemical gradient and simultaneously pumps K^+ into the cell against its chemical gradient, the intracellular K^+ concentration remains high and the intracellular Na^+ concentration remains low. This pump, fueled by an Na^+,K^+ -ATPase enzyme that hydrolyzes ATP for energy, is bound to the membrane. It requires both Na^+ and K^+ to function and can transport three Na^+ ions outward for two K^+ ions inward. Therefore the pump can be electrogenic and generate a net outward movement of positive charges. The rate of Na^+-K^+ pumping to maintain the same ionic gradients must increase as the heart rate increases because the cell gains a slight amount of Na^+ and loses a slight amount of K^+ with each depolarization. Cardiac glycoside-induced block of Na^+,K^+ -ATPase increases contractility through an increase in intracellular Na^+ concentration, which in turn reduces Ca^{2+} extrusion through the Na^+/Ca^{2+} exchanger (see later) and ultimately increases myocyte contractility.⁵³

Phase 0: Upstroke or Rapid Depolarization. A stimulus delivered to excitable tissue evokes an action potential characterized by a sudden change in voltage caused by transient depolarization followed by repolarization. The action potential is conducted throughout the heart and is responsible for initiating each heartbeat. Electrical changes in action potential follow a relatively fixed time and voltage relationship that differs according to specific cell types (Fig. 33-17). In nerve, the entire process takes several milliseconds, whereas action potentials in human cardiac fibers last several hundred milliseconds. Normally, the action potential is independent of the size of the depolarizing stimulus if the latter exceeds a certain threshold potential. Small subthreshold depolarizing stimuli depolarize the membrane in

TABLE 33-2 Properties of Transmembrane Potentials in Mammalian Hearts

PROPERTY	SINUS NODAL CELL	ATRIAL MUSCLE CELL	AV NODAL CELL	PURKINJE FIBER	VENTRICULAR MUSCLE CELL

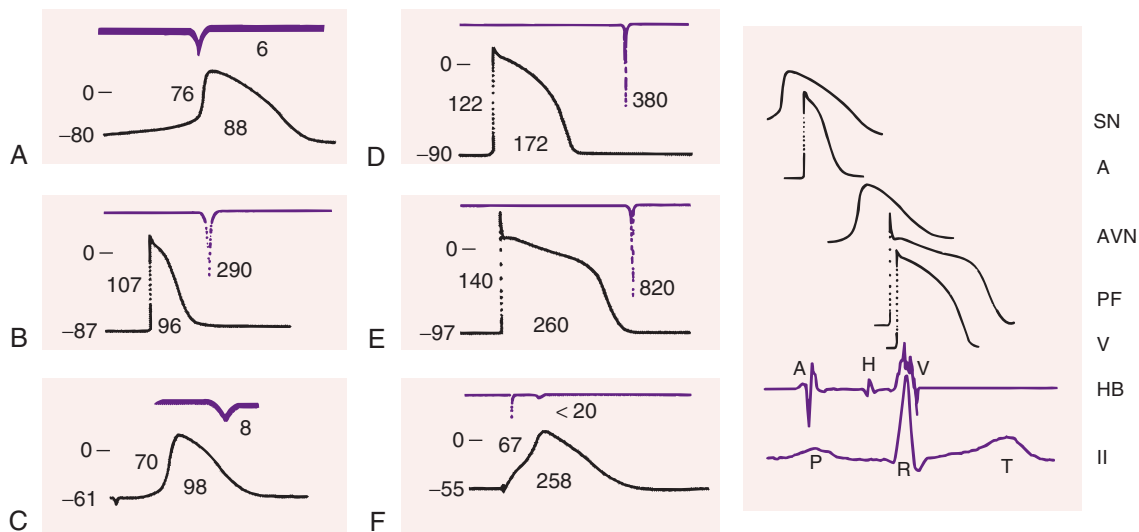

FIGURE 33-17 Action potentials recorded from different tissues in the heart (left) remounted along with a His bundle recording and scalar electrocardiogram from a patient (right) to illustrate the timing during a single cardiac cycle. In panels **A** to **F**, the top tracing is dV/dt of phase 0 and the second tracing is the action potential. For each panel, the numbers (from left to right) indicate maximum diastolic potential (mV), action potential amplitude (mV), action potential duration at 90% of repolarization (milliseconds), and \dot{V}_{\max} of phase 0 (V/sec). Zero potential is indicated by the short horizontal line next to the zero on the upper left of each action potential. **A**, Rabbit sinoatrial node. **B**, Canine atrial muscle. **C**, Rabbit AV node. **D**, Canine ventricular muscle. **E**, Canine Purkinje fiber. **F**, Diseased human ventricle. Note that the action potentials recorded in **A**, **C**, and **F** have reduced resting membrane potentials, amplitudes, and \dot{V}_{\max} relative to the other action potentials. A = atrial muscle potential; AVN = atrioventricular nodal potential; HB = His bundle recording; II = lead II; PF = Purkinje fiber potential; SN = sinus nodal potential; V = ventricular muscle potential. Horizontal calibration on the left: 50 milliseconds for **A** and **C**, 100 milliseconds for **B**, **D**, **E**, and **F**; 200 milliseconds on the right. Vertical calibration on the left: 50 mV; horizontal calibration on the right: 200 milliseconds. (Modified from Gilmour RF Jr, Zipes DP: *Basic electrophysiology of the slow inward current*. In Antman E, Stone PH [eds]: *Calcium Blocking Agents in the Treatment of Cardiovascular Disorders*. Mount Kisco, NY, Futura, 1983, pp 1-37.)

proportion to the strength of the stimulus. However, when the stimulus is sufficiently intense to reduce membrane potential to a threshold value in the range of -70 to -65 mV for normal Purkinje fibers, more intense stimuli do not produce larger action potential responses, and an "all-or-none" response results. In contrast, hyperpolarizing pulses, stimuli that render the membrane potential more negative, elicit a response proportional to the strength of the stimulus.

Mechanism of Phase 0. The upstroke of the cardiac action potential in atrial and ventricular muscle and His-Purkinje fibers is the result of a sudden increase in membrane conductance of Na^+ . An externally applied stimulus or a spontaneously generated local membrane circuit current in advance of a propagating action potential depolarizes a sufficiently large area of membrane at a sufficiently rapid rate to open the Na^+ channels and depolarize the membrane further. When the stimulus activates enough Na^+ channels, Na^+ ions enter the cell down their electrochemical gradient. The excited membrane no longer behaves like a K^+ electrode, that is, exclusively permeable to K^+ , but more closely approximates an Na^+ electrode, and the membrane moves toward the Na^+ equilibrium potential.

The rate at which depolarization occurs during phase 0, that is, the maximum rate of change in voltage over time, is indicated by the expression dV/dt_{\max} or \dot{V}_{\max} (see Table 33-2), which is a reasonable approximation of the rate and magnitude of Na^+ entry into the cell

and a determinant of conduction velocity for the propagated action potential. The transient increase in sodium conductance lasts 1 to 2 milliseconds. The action potential, or more properly the Na^+ current (I_{Na}), is said to be regenerative; that is, intracellular movement of a little Na^+ depolarizes the membrane more, which increases conductance of Na^+ more and allows more Na^+ to enter, and so on. As this process is occurring, however, $[\text{Na}^+]_i$ and positive intracellular charges increase and reduce the driving force for Na^+ . When the equilibrium potential for Na^+ (E_{Na}) is reached, Na^+ no longer enters the cell; that is, when the driving force acting on the ion to enter the cell balances the driving force acting on the ion to exit the cell, no current flows. In addition, Na^+ conductance is time dependent, so when the membrane spends some time at voltages less negative than the resting potential, Na^+ conductance decreases (inactivation; see earlier). Therefore an intervention that reduces membrane potential for a time (acute myocardial ischemia), but not to threshold, partially inactivates Na^+ channels, and if the threshold is now achieved, the magnitude and rate of Na^+ influx are reduced, which causes conduction velocity to slow.

In cardiac Purkinje fibers, sinoatrial cells, and to a lesser extent, ventricular muscle, two different populations of Na^+ channels exist: the tetrodotoxin (TTX)-sensitive, neuronal Na^+ channel isoform (Nav1.1) and the TTX-resistant Nav1.5 isoform, the latter being the

predominant isoform in cardiac muscle. Although the precise role of Nav1.1 channels in ventricular or atrial cardiomyocytes has not been defined, this channel is an important modulator of sinoatrial node pacemaking⁵⁴ and in determining Purkinje myocyte action potential duration.

Upstroke of the Action Potential. In normal atrial and ventricular muscle and in fibers in the His-Purkinje system, action potentials have very rapid upstrokes with a large V_{\max} and are called fast responses. Action potentials in the normal sinoatrial and AV nodes and many types of diseased tissue have very slow upstrokes with a reduced V_{\max} and are called slow responses (Table 33-3; see also Figs. 33-4, 33-7, and 33-17). Upstrokes of slow responses are mediated by a slow inward, predominantly L-type voltage-gated (Cav) Ca^{2+} current ($I_{\text{Ca,L}}$) rather than by the fast inward I_{Na} . These potentials have been termed *slow response potentials* because the time required for activation and inactivation of the slow inward current ($I_{\text{Ca,L}}$) is approximately an order of magnitude slower than that for the fast inward Na^+ current (I_{Na}). Recovery from inactivation also takes longer. Calcium entry and $[\text{Ca}^{2+}]_i$ help promote inactivation. The slow channel requires more time after a stimulus to be reactivated. In fact, recovery of excitability outlasts full restoration of maximum diastolic potential, which means that even though the membrane potential has returned to normal, the cell has not recovered excitability completely because the latter depends on the elapse of a certain amount of time (i.e., is time dependent) and not just on recovery of a particular membrane potential (i.e., voltage dependent), a phenomenon termed *postrepolarization refractoriness*.

The threshold for activation of $I_{\text{Ca,L}}$, that is, the voltage that the cell must reach to “turn on” the slow inward current, is about -30 to -40 mV. In fibers of the fast response type, $I_{\text{Ca,L}}$ is normally activated during phase 0 by the regenerative depolarization caused by the fast sodium current. Current flows through both fast and slow channels during the latter part of the action potential upstroke. However, $I_{\text{Ca,L}}$ is much smaller than the peak Na^+ current and therefore contributes little to the action potential until the fast Na^+ current is inactivated after completion of phase 0. Thus $I_{\text{Ca,L}}$ affects mainly the plateau of action potentials recorded in atrial and ventricular muscle and His-Purkinje fibers. In addition, $I_{\text{Ca,L}}$ may play a prominent role in partially depolarized cells in which the fast Na^+ channels have been inactivated if conditions are appropriate for slow-channel activation.

Ca^{2+} entry through activated L-type Cav channels triggers release of Ca^{2+} from SR stores and is an essential component of cardiac excitation-contraction coupling in atrial and ventricular myocardium (see Chapter 21). L-type Cav channels are also expressed in sinoatrial and AV nodal cells, where they play a role in controlling automaticity and action potential propagation, respectively. Cardiac L-type Cav channels undergo rapid voltage- and Ca^{2+} -dependent inactivation, the time course of which importantly affects the action potential waveform and the time course of repolarization. Although T-type Cav channels have not been detected in human myocardium, experimental evidence in animals has suggested that these channels play an important role in determining sinoatrial node automaticity and AV nodal conduction.³⁰ Whether Ca^{2+} influx through open T-type channels provides a sufficient trigger for release of Ca^{2+} from the SR is controversial. The density of T-type Ca^{2+} channels has been found to be increased in myocytes from hearts with experimentally induced hypertrophy, but the role of enhanced T-type channel density under these conditions remains to be determined.

Other significant differences exist between the fast and slow channels. Drugs that elevate cAMP levels, such as beta adrenoceptor agonists, phosphodiesterase inhibitors such as theophylline, and the lipid-soluble derivative of cAMP, dibutyryl cAMP, increase $I_{\text{Ca,L}}$. Binding of the beta adrenoceptor agonist to specific sarcolemmal receptors facilitates the dissociation of two subunits of a regulatory protein (G protein; see Chapter 21), one of which (G_s) activates adenylate cyclase and thus increases intracellular levels of cAMP. The latter binds to a regulatory subunit of a cAMP-dependent protein kinase that promotes phosphorylation of specific phosphorylation sites on the channel protein, which ultimately results in an enhanced open-state probability of the channel. Although Nav channels are sensitive to increases in cAMP, the net effect (decrease versus increase) appears to be species dependent.

Acetylcholine reduces $I_{\text{Ca,L}}$ by decreasing adenylate cyclase activity. However, acetylcholine stimulates the accumulation of cGMP. cGMP has negligible effects on basal $I_{\text{Ca,L}}$ but decreases the $I_{\text{Ca,L}}$ levels that have been elevated by beta adrenoceptor agonists. This effect is mediated by cAMP hydrolysis through a cGMP-stimulated cyclic nucleotide phosphodiesterase.

Differences Between Channels. Fast and slow channels can be differentiated on the basis of their pharmacologic sensitivity. Drugs that block the slow channel with a fair degree of specificity include verapamil, nifedipine, diltiazem, and D-600 (a methoxy derivative of verapamil). Antiarrhythmic agents such as lidocaine, quinidine, procainamide, and disopyramide (see Chapter 35) affect the fast channel and not the slow channel.

Normal action potentials recorded from the sinus node and the compact node of the AV junction have a reduced resting membrane potential, action potential amplitude, overshoot, upstroke, and conduction velocity when compared with action potentials in muscle or Purkinje fibers (see Figs. 33-7 and 33-17).

Slow-channel blockers suppress sinus and AV nodal action potentials. The prolonged time for reactivation of $I_{\text{Ca,L}}$ probably accounts for the fact that sinoatrial and AV nodal cells remain refractory longer than the time that it takes for full voltage repolarization to occur. Thus premature stimulation immediately after the membrane potential reaches full repolarization leads to action potentials with reduced amplitudes and upstroke velocities. Therefore slow conduction and prolonged refractoriness are characteristic features of nodal cells. These cells also have a reduced “safety factor for conduction” (see earlier), which means that the stimulating efficacy of the propagating impulse is low and conduction block occurs easily.

Inward Currents. Thus I_{Na} and $I_{\text{Ca,L}}$ represent two important inward currents. Another important inward current is I_f , also called the pacemaker or “funny” current.⁵⁵ This current is activated by hyperpolarization and is carried by Na^+ and K^+ . It generates phase 4 diastolic depolarization in the sinoatrial node. I_f modulation is one major mechanism whereby beta-adrenergic and cholinergic neurotransmitters regulate cardiac rhythm under physiologic conditions. Catecholamines increase the probability of channel opening by shifting the channel’s activation curve to more positive potentials, which leads to increased current availability for the generation of diastolic depolarization and hence steepens its rate. Cholinergic action, in general, exerts the opposite effect.⁴⁶ Fish oil depresses I_f .⁵⁶ The electrophysiologic changes accompanying acute myocardial ischemia may represent a depressed form of a fast response in the center of the ischemic zone and a slow response in the border area. Probable slow-response activity has been shown in myocardium resected from patients undergoing surgery for recurrent ventricular tachyarrhythmias (see Fig. 33-17F). Whether and how slow responses play a role in the genesis of ventricular arrhythmias in these patients have not been established.

Phase 1: Early Rapid Repolarization. Following phase 0, the membrane repolarizes rapidly and transiently to almost 0 mV (early notch), partly because of inactivation of I_{Na} and concomitant activation of several outward currents.

I_{to} . The 4-aminopyridine-sensitive transient outward K^+ current, commonly termed I_{to} (or I_{to1}), is turned on rapidly by depolarization and then rapidly inactivates. Both the density and recovery of I_{to} from inactivation exhibit transmural gradients in the left ventricular free wall, with the density decreasing and reactivation becoming progressively prolonged from epicardium to endocardium.²⁹ Transmural differences in the expression of KChIP2, the auxiliary subunit to Kv4.3 pore-forming alpha subunits, appears to be the primary determinant of the transmural gradient in I_{to} properties and densities in the human heart.⁵⁷ This gradient gives rise to regional differences in action potential shape, with increasingly slower phase 1 restitution kinetics and diminution of the notch along the transmural axis (Fig. e33-4).

These regional differences might create transmural voltage gradients, specifically at higher rates, thereby increasing dispersion of repolarization, a putative arrhythmogenic factor (Brugada syndrome; see Chapters 32 and 37). However, elimination of the physiologic repolarization gradient appears to be similarly arrhythmogenic.⁵⁷ Downregulation of I_{to} is at least partially responsible for slowing of phase 1 repolarization in failing human myocytes. Studies have demonstrated that these changes in the phase 1 notch of the cardiac action potential cause a reduction in the kinetics and peak amplitude of the action potential-evoked intracellular Ca^{2+} transient because of failed recruitment and synchronization of SR Ca^{2+} release through $I_{\text{Ca,L}}$ (Fig. e33-5). Thus modulation of I_{to} appears to play a significant physiologic role in controlling cardiac excitation-contraction coupling,⁵⁸ and it remains to be determined whether transmural differences in phase 1 repolarization translate into similar differences in regional contractility.

$I_{\text{Cl,Ca}}$. The 4-aminopyridine-resistant, Ca^{2+} -activated chloride current $I_{\text{Cl,Ca}}$ (or I_{to2}) also contributes a significant outward current during phase 1 repolarization.⁵⁹ This current is activated by the action potential-evoked intracellular Ca^{2+} transient. Therefore interventions that augment the amplitude of the Ca^{2+} transient associated with the twitch (such as beta-adrenergic receptor stimulation) also enhance

FIGURE e33-4 Action potential plots demonstrating differences in the action potential shape of human ventricular myocytes of subepicardial (**A**) and subendocardial (**B**) origin. Subepicardial myocytes present a prominent notch during phase 1 repolarization of the action potential, most likely caused by a larger I_{to} in these cells. The notch is absent in subendocardial cells. The peak plateau potential is higher in subendocardial than in subepicardial myocytes, and the action potential duration tends to be shorter in subepicardial cells. **C**, Transmembrane action potential in a human ventricular cardiomyocyte of a failing heart. Note loss of the prominent phase 1 notch and delayed repolarization. Recording temperature = 35°C; V_m = membrane potential. (**A, B**, From Näbauer M, Beuckelmann DJ, Überfuhr P, Steinbeck G: Regional differences in current density and rate-dependent properties of the transient outward current in subepicardial and subendocardial myocytes of human left ventricle. *Circulation* 93:168, 1996. FIGURE e33-5 Diminution of phase 1 amplitude ("notch") causes asynchronous SR Ca^{2+} release. Normal cardiomyocytes were voltage-clamped with action potential profiles having a normal or congestive heart failure wave shape, and local changes in intracellular calcium were recorded simultaneously. When the myocyte was clamped with a normal action potential profile having the early phase 1 repolarization notch (**left**), there was uniform Ca^{2+} release. However, when a congestive heart failure action potential profile without early rapid phase 1 repolarization was used, Ca^{2+} release was dyssynchronous. This dyssynchrony causes slowing in the rate of rise of the Ca^{2+} transient and loss of spatial and temporal release uniformity. F/F_0 = fluorescence of the Ca^{2+} indicator normalized to its baseline fluorescence. (From Harris DM, Mills GD, Chen X, et al: Alterations in early action potential repolarization causes localized failure of sarcoplasmic reticulum Ca^{2+} release. *Circ Res* 96:543, 2005. By permission of the American Heart Association.)

TABLE 33-3 Synopsis of Transsarcolemmal Ionic Currents in Mammalian Cardiac Myocytes

CURRENT	SUBUNIT	FUNCTIONAL PROPERTIES
I_{Na}	Nav1.5, Nav1.1, Nav1.3, Nav1.6, Nav1.8 (alpha subunits)	TTX-resistant (Nav1.5, Nav1.8) and TTX-sensitive (Nav1.1, Nav1.3, Nav1.6) voltage-gated currents; Nav1.5 is the major cardiac isoform; neuronal Na^+ channel isoforms contribute to sinoatrial node pacemaking and ventricular repolarization
$I_{Ca,L}$	Cav1.2 (alpha subunit)	L-type (long lasting, large conductance) Ca^{2+} currents through voltage-gated Ca^{2+} (Cav) channels blocked by dihydropyridine-type antagonists (e.g., nifedipine), phenylalkylamines (e.g., verapamil), benzothiazepines (e.g., diltiazem), and various divalent ions (e.g., Cd^{2+}); activated by dihydropyridine-type agonists (e.g., Bay K 8644); responsible for phase 0 depolarization and propagation in sinoatrial and AV nodal tissue and contributing to the plateau of atrial, His-Purkinje, and ventricular cells; main trigger of Ca^{2+} release from the SR (Ca^{2+} -induced Ca^{2+} release); the noninactivating or "window" component underlies EADs
$I_{Ca,T}$	Cav3.1/alpha _{1G} (alpha subunit)	T-type (transient current, tiny conductance) Ca^{2+} currents through Cav channels blocked by mibefradil and efonidipine but insensitive to dihydropyridines; may contribute an inward current to the later phase of phase 4 depolarization in pacemaker cells and action potential propagation in AV nodal cells; role in triggering Ca^{2+} -induced Ca^{2+} release uncertain
I_f	HCN4 (alpha subunit)	Hyperpolarization-activated "funny" current carried by Na^+ and K^+ in sinoatrial and AV nodal cells and His-Purkinje cells; involved in generating phase 4 depolarization; increases the rate of impulse initiation in pacemaker cells
I_{K1}	Kir2.1 (alpha subunit)	K^+ current through inwardly rectifying K^+ (Kir) channels, voltage-dependent block by Ba^{2+} at micromolar concentrations; responsible for maintaining resting membrane potential in atrial, His-Purkinje, and ventricular cells; channel activity is a function of both membrane potential and $[K^+]_o$; inward rectification appears to result from depolarization-induced internal block by Mg^{2+} and neutral or positively charged amino acid residues in the cytoplasmic channel pore
$I_{K,G}$ ($I_{K,ACh}$, $I_{K,Ade}$)	Kir3.1/Kir3.4 (alpha subunit)	Inwardly rectifying K^+ current activated by muscarinic (M_2) and purinergic (type 1) receptor stimulation via GTP regulatory (G) protein signal transduction; expressed in sinoatrial and AV nodal cells and atrial cells, where it causes hyperpolarization and action potential shortening; activation causes negative chronotropic and dromotropic effects
I_{Ks}	KvLQT1 (alpha subunit)/minK (beta subunit)	K^+ current carried by a voltage-gated K^+ (Kv) channel (delayed rectifier K^+ channel); plays a major role in determining phase 3 of the action potential
I_{Kr}	hERG (alpha subunit)/MiRP1 (beta subunit)	Rapidly activating component of delayed rectifier K^+ current; I_{Kr} specifically blocked by dofetilide and sotalol in a reverse use-dependent manner; inward rectification of I_{Kr} results from depolarization-induced fast inactivation; plays a major role in determining the action potential duration
I_{Kur}	Kv1.5 (alpha subunit)	K^+ current through a Kv channel with ultrarapid activation but ultraslow inactivation kinetics; expressed in atrial myocytes; determines the action potential duration
$I_{K,Ca}$	SK2 (alpha subunit)	K^+ current through small-conductance Ca^{2+} -activated channels; blocked by apamine and dequalinium chloride; expressed in human atrial and ventricular myocytes; determines the action potential duration; upregulated in failing cardiomyocytes
I_{to} (I_{to1} , I_A)	Kv4.3 (alpha subunit)/KChIP2 (beta subunit)	Transient outward K^+ current through voltage-gated (Kv) channels; exhibits fast activation and inactivation and recovery kinetics; blocked by 4-aminopyridine in a reverse use-dependent manner; contributes to the time course of phase 1 repolarization; transmural differences in I_{to} properties contribute to regional differences in early repolarization
$I_{Cl,Ca}$ (I_{to2})	?	4-Aminopyridine-resistant transient outward current carried by Cl^- ions; activated by an increase in intracellular calcium level; blocked by stilbene derivatives (SITS, DIDS); contributes to the time course of phase 1 repolarization; may underlie spontaneous transient inward currents under conditions of Ca^{2+} overload; molecular correlate uncertain
$I_{Cl,cAMP}$?	Time-independent chloride current regulated by the cAMP/adenylylase pathway; slightly depolarizes resting membrane potential and significantly shortens the action potential duration; antagonizes action potential prolongation associated with beta-adrenergic stimulation of $I_{Ca,L}$
$I_{Cl,swell}$ or $I_{Cl,vol}$?	Outwardly rectifying, swelling-activated Cl^- current; inhibited by 9-anthracene carboxylic acid; activation causes resting membrane depolarization and action potential shortening
$I_{K,ATP}$	Kir6.2 (alpha subunit)/SUR	Time-independent K^+ current through Kir channels activated by a fall in intracellular ATP concentration; inhibited by sulfonylurea drugs, such as glibenclamide; activated by pinacidil, nicorandil, cromakalim; causes shortening of the action potential duration during myocardial ischemia or hypoxia
$I_{Cl,swell}$?	Inwardly rectifying, swelling-activated cation current; permeable to Na^+ and K^+ ($P_{Na}/P_K = 8$); inhibited by Gd^{3+} ; depolarizes resting membrane potential and prolongs terminal (phase 3) repolarization
$I_{Na/Ca}$	NCX1.1	Current carried by Na^+/Ca^{2+} exchanger; causes net Na^+ outward current and Ca^{2+} inward current (reverse mode) or net Na^+ inward and Ca^{2+} outward current (3 Na^+ for 1 Ca^{2+}); direction of Na^+ flux depends on membrane potential and intracellular and extracellular concentrations of Na^+ and Ca^{2+} ; Ca^{2+} influx mediated by $I_{Na/Ca}$ can trigger SR Ca^{2+} release; underlies I_{ti} (transient inward current) under conditions of intracellular Ca^{2+} overload
$I_{Na/K}$	Alpha subunit/beta subunit	Na^+ outward current generated by Na^+, K^+ -ATPase (stoichiometry: 3 Na^+ leave and 2 K^+ enter); inhibited by digitalis
I_{ti}	?	Transient inward current activated by Ca^{2+} waves; I_{ti} possibly reflects 3 Ca^{2+} -dependent components: I_{NCX} , $I_{Cl,Ca}$, and a TRPM4 (transient receptor potential cation channel, member 4 gene)-mediated current
Electroneutral Ion-Exchanging Proteins		
Ca^{2+} -ATPase		Extrudes cytosolic calcium
Na/H	Cardiac myocytes express isoform NHE1	Exchanges intracellular H^+ for extracellular Na^+ ; specifically inhibited by the benzoylguanidine derivatives HOE 694 and HOE 642; inhibition causes intracellular acidification
$Cl^-HCO_3^-$		Exchanges intracellular HCO_3^- for external Cl^- ; inhibited by SITS
$Na^+-K^+-2Cl^-$		Cotransporter blocked by amiloride

DIDS = 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid; SITS = 4-acetamido-4'-isothiocyanatostilbene-2,2'-disulfonic acid.

outward $I_{Cl, Ca}$. It is not currently known whether human cardiac myocytes express Ca^{2+} -activated chloride channels. Other, time-independent chloride currents may also play a role in determining the time course of early repolarization, such as the cAMP- or swelling-activated chloride conductances $I_{Cl, cAMP}$ and $I_{Cl, swell}$.

Na/Ca Exchanger. A third current contributing to early repolarization is Na^+ outward movement through the Na^+/Ca^{2+} exchanger operating in reverse mode (see Fig. 33-16).⁶⁰ Overexpression of the exchanger in transgenic mice caused accentuation of the early notch in left ventricular myocytes.

Sometimes, a transient depolarization follows phase 1 repolarization. This notch is well defined and separated from phase 2 in Purkinje fibers and left ventricular epicardial and midmyocardial myocytes (see Fig. e33-4).

Phase 2: Plateau. During the plateau phase, which may last several hundred milliseconds, membrane conductance of all ions falls to rather low values. Thus less change in current is required near plateau levels than near resting potential levels to produce the same changes in transmembrane potential. The plateau is maintained by competition between the outward current carried by K^+ and Cl^- ions and the inward current carried by Ca^{2+} moving through open L-type Ca^{2+} channels and Na^+ being exchanged for internal Ca^{2+} by the Na^+/Ca^{2+} exchanger operating in forward mode. After depolarization, potassium conductance falls to plateau levels as a result of inward rectification despite the large electrochemical driving force on K^+ ions.

Rectification simply means that membrane conductance changes with voltage. Specifically, inward rectification means that K^+ channels are open at negative potentials but closed at less negative or positive voltages. Membrane depolarization-induced internal block by intracellular ionized magnesium is thought to underlie inward rectification of cardiac I_{K1} channels. Inward rectification can also be induced by neutral and positively charged amino acid residues in the cytoplasmic channel pore that is formed by four Kir2.1 subunits.⁶¹ The mechanism underlying rectification of the rapid component of the delayed rectifier K^+ current (I_{Kr}) in cardiac cells is the inactivation that channels rapidly undergo during depolarizing pulses. More I_{Kr} channels enter the inactivated state with stronger depolarizations, thereby causing inward rectification. This fast inactivation mechanism is sensitive to changes in extracellular K^+ in the physiologic range, with inactivation being more accentuated at low extracellular K^+ concentrations. Thus hypokalemia would decrease outward I_{Kr} , thereby prolonging the action potential duration.

Outward K^+ movement carried by the slow component of the delayed rectifier K^+ current (I_{Ks}) also contributes to plateau duration: (1) I_{Ks} density has been shown to be correlated with the action potential duration, and (2) isolated defects in the KvLQT1 subunit, which in combination with the I_{Ks} subunit (minK) reconstitutes the cardiac I_{Ks} current, are associated with abnormally prolonged ventricular repolarization (LQTS type 1; see Chapters 32 and 37). Although I_{Ks} activates slowly in comparison to the action potential duration, it is only slowly inactivated. Therefore increases in heart rate can cause this activation to accumulate during successive depolarizations, and cumulative activation can determine the contribution to repolarization of K^+ currents that are active during the plateau of the action potential. In conditions of reduced intracellular ATP concentration (e.g., hypoxia, ischemia), K^+ efflux through activated K_{ATP} channels is enhanced, thereby shortening the plateau phase of the action potential. Other ionic mechanisms that control plateau potential and duration include the kinetics of inactivation of the L-type Ca^{2+} current. Reduced efficiency of intracellular free Ca^{2+} in inducing Ca^{2+} -dependent inactivation, such as in myocytes from hypertrophic hearts, can result in delayed repolarization. Steady-state components of both I_{Na} and $I_{Ca,L}$ (window currents) also shape the plateau phase.³³ Na^+, K^+ -ATPase generates a net outward current by pumping out three Na^+ ions in exchange for two K^+ ions. Noninactivating chloride currents, such as $I_{Cl, swell}$ and $I_{Cl, cAMP}$, may produce significant outward currents during the plateau phase under certain conditions, thereby significantly shortening the action potential duration. A nonselective, swelling-induced cation current has been shown to cause prolongation of action potentials in myocytes from failing ventricles.

Phase 3: Final Rapid Repolarization. In this portion of the action potential, repolarization proceeds rapidly at least in part because of two currents: time-dependent inactivation of $I_{Ca,L}$, with a decrease in the intracellular movement of positive charges, and activation of repolarizing K^+ currents, including the slow and rapid components of the delayed rectifier K^+ currents I_{Ks} and I_{Kr} and the inwardly rectifying K^+ currents I_{K1} and $I_{K_{ACh}}$, which all cause an increase in the movement of positive charges out of the cell. The net membrane current becomes

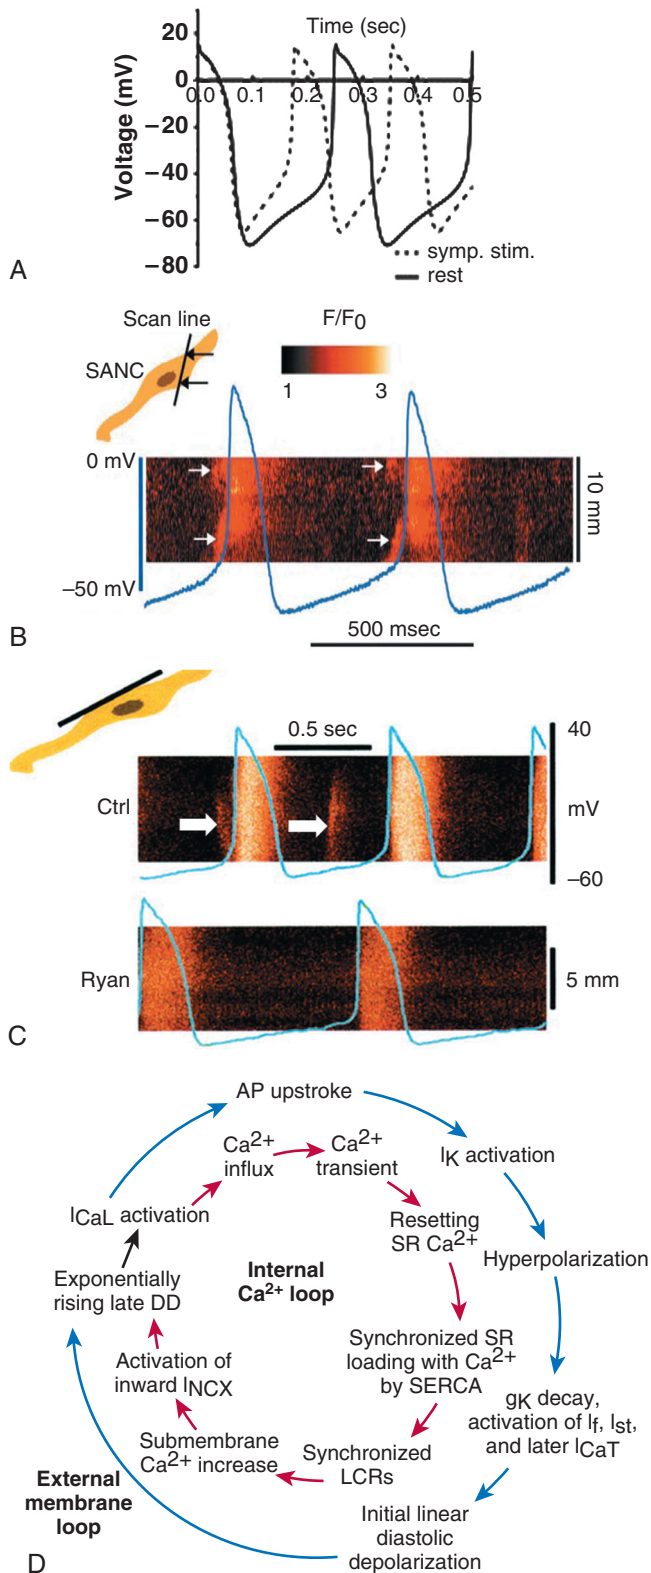

more outward, and the membrane potential shifts to the resting potential. A small-conductance Ca^{2+} -activated K^+ current, $I_{K_{Ca}}$, is expressed in human atrial myocytes, where it controls the time course of phase 3 repolarization.⁶² Loss-of-function mutations in the human ether-a-go-go-related gene (*HERG*), which is responsible for I_{Kr} , prolong phase 3 repolarization, thereby predisposing to the development of torsades de pointes. Macrolide antibiotics such as erythromycin, antihistamines such as terfenadine, and antifungal drugs such as ketoconazole inhibit I_{Kr} and have been implicated in the acquired form of LQTS (see Chapters 32 and 39). A decrease in I_{K1} activity, as is the case in left ventricular myocytes from failing hearts, causes prolongation of the action potential by slowing of phase 3 repolarization and resting membrane depolarization. A reduction in the outward potassium current through open inwardly rectifying K^+ channels renders the failing cardiomyocyte more susceptible to the induction of DADs triggered by spontaneous intracellular Ca^{2+} release events and therefore plays a major role in arrhythmogenesis in the failing heart (see Fig. 33-20).

Phase 4: Diastolic Depolarization. Under normal conditions the membrane potential of atrial and ventricular muscle cells remains steady throughout diastole. I_{K1} is the current responsible for maintaining the resting potential near the K^+ equilibrium potential in atrial, His-Purkinje, and ventricular cells. I_{K1} is the inward rectifier and shuts off during depolarization. In other fibers found in certain parts of the atria, in the muscle of the mitral and tricuspid valves, in His-Purkinje fibers, and in the sinoatrial node and portions of the AV nodal tract, the resting membrane potential does not remain constant in diastole but gradually depolarizes (see Figs. 33-4, 33-7, and 33-17A). The property possessed by spontaneously discharging cells is called phase 4 diastolic depolarization; when it leads to initiation of action potentials, automaticity results. The discharge rate of the sinoatrial node normally exceeds the discharge rate of other potentially automatic pacemaker sites and thus maintains dominance of the cardiac rhythm. The discharge rate of the sinoatrial node is usually more sensitive than the discharge rate of ventricular muscle cells to the effects of norepinephrine and acetylcholine. Normal or abnormal automaticity at other sites can cause discharge at rates faster than the sinoatrial nodal discharge rate and can thus usurp control of the cardiac rhythm for one cycle or many (see Chapter 34).

Normal Automaticity

Two models of sinoatrial node pacemaking have been proposed. In the first model, HCN channels are activated by hyperpolarizations in the normal range of diastolic membrane potentials. During the hyperpolarized diastolic membrane potential between consecutive action potentials, HCN channels will increase their probability of being open (see earlier). Open HCN channels conduct both Na^+ and K^+ , but at these negative membrane potentials they let mainly Na^+ into the cells. It is this inward Na^+ current through HCN channels (together with inflow of Ca^{2+} through voltage-activated Ca^{2+} channels, inward currents through Na^+/Ca^{2+} exchangers, and decaying outward K^+ currents; see Fig. 33-16) at diastolic membrane potentials that is thought to depolarize the pacemaker cells to threshold and thus trigger the next action potential and generate a periodically firing pacemaker (see Fig. 33-17A).⁶³

In the model proposed by proponents of Ca^{2+} oscillations operating as the primary pacemaking mechanism (" Ca^{2+} clock"), periodic increases in $[Ca^{2+}]_i$ serve as an internal generator (" $calcium clock$ ") of rhythmic signals that are transformed into changes in membrane voltage via modulation of calcium-sensitive ion channels and transporters in the outer membrane (" $membrane clock$ ").⁶⁴ This novel concept is illustrated in Figure 33-18, in which simultaneous $[Ca^{2+}]_i$ and action potential measurements in isolated sinoatrial myocytes are used as an example. Local submembrane increases in $[Ca^{2+}]_i$ (denoted by the white arrows in Fig. 33-18B, C) occurring during the later part of the spontaneous diastolic depolarization (transmembrane action potentials are shown in blue) precede the rapid upstroke of the action potential. These local submembrane increases in $[Ca^{2+}]_i$ are abolished by a specific blocker of the SR Ca^{2+} release channel, ryanodine (Ryan), concurrent with slowing of the beating frequency by this drug. The periodic SR Ca^{2+} release events rhythmically activate the Na^+/Ca^{2+} exchange inward (i.e., depolarizing) current (I_{NCX} ; Fig. 33-18D), which then results in an exponential increase in membrane potential that prompts activation of surface membrane L-type Ca^{2+} channels to initiate an action potential (see Fig. 33-18D). Thus the Na^+/Ca^{2+} exchanger operating in forward mode plays an essential role in converting the primary intracellular Ca^{2+} signals into membrane (i.e., voltage) signals. In this novel model of sinoatrial node pacemaking, spontaneous SR

Ca²⁺ release-induced membrane excitation initiates the sinoatrial node cell duty cycle, as schematically illustrated in Figure 33-18D. Once an action potential has been initiated, two highly interacting, concurrent series of events proceed during a normal sinoatrial node cell cycle (see Fig. 33-18D). In one event series (delimited to the outer membrane), depolarization-induced activation of the delayed rectifier K⁺ current I_K (see Table 33-3) leads to membrane hyperpolarization, which is followed by slow diastolic depolarization via activation of a number of inward currents, including I_f and I_{CaT} (see Table 33-3). In a

FIGURE 33-18 Sympathetic stimulation of heart rate in the sinoatrial node.

A, Simulated sinoatrial node action potentials during baseline (solid line) and sympathetic stimulation (dashed line). Sympathetic stimulation increases the rate of diastolic depolarization and shifts the maximum diastolic potential to a less negative value, thereby accelerating action potential firing. **B-D**, Spontaneous SR Ca²⁺ release events trigger membrane excitation in sinoatrial node myocytes. **B**, **C**, Confocal line scan images of Ca²⁺ signals measured in spontaneously beating rabbit sinoatrial node cells with different orientation of the scanning line simultaneously with recording (blue lines) of transmembrane action potentials. **B**, Transversal orientation of the scan line (inset). Arrows in the confocal image show the local Ca²⁺ release in the submembrane space during late diastolic depolarization that precedes the rapid upstroke of the action potential. **C**, The scanned line was oriented parallel to the longitudinal axis of the cell near the cell's edge (inset). The specific blocker of the SR Ca²⁺ release channel, ryanodine (Ryan), slows the beating rate and is accompanied by abolition of local subsarcolemmal Ca²⁺ release during diastolic depolarization (arrows). **D**, Model of sinoatrial node cell pacemaking as suggested by Maltsev and coworkers. I_{NCX} = Na⁺/Ca²⁺ exchange current; DD = diastolic depolarization; LCR = local Ca²⁺ release. (**A**, From Larsson HP. How is the heart rate regulated in the sinoatrial node? Another piece to the puzzle. *J Gen Physiol* 136:237, 2010; **B-D**, from Maltsev VA, Vinogradova TM, Lakatta EG. The emergence of a general theory of the initiation and strength of the heartbeat. *J Pharmacol Sci* 100:338, 2006.)

second, parallel cycle of events, action potential-induced SR Ca²⁺ release is followed by Ca²⁺ reuptake into the SR, which subsequently gives rise to multifocal, synchronized spontaneous Ca²⁺ release events culminating in an increase in inward I_{NCX}. The role of late diastolic spontaneous SR Ca²⁺ release events in triggering the sinoatrial node action potential has recently been confirmed in canine hearts in situ (Fig. e33-6).⁶⁵

The rate of sinoatrial nodal discharge can be varied by several mechanisms in response to autonomic or other influences. The pacemaker locus can shift within or outside the sinoatrial node to cells discharging faster or more slowly.⁶³ If the pacemaker site remains the same, alterations in the slope of the diastolic depolarization, maximum diastolic potential, or threshold potential can speed or slow the discharge rate (Fig. 33-18A). For example, if the slope of diastolic depolarization steepens and if the resting membrane potential becomes less negative or the threshold potential more negative (within limits), the discharge rate increases. Opposite changes slow the discharge rate. The molecular mechanism that is primarily responsible for acceleration of the sinoatrial node discharge rate has been highly controversial. Proponents of the HCN pacemaker role consider an increase in inward HCN current via a shift of the HCN channel activation curve to more depolarized potentials the primary regulatory mechanism.^{3,65} In contrast, proponents of the Ca²⁺ clock model have suggested protein kinase A-mediated phosphorylation of Ca²⁺-handling proteins (ryanodine receptor, phospholamban [see Chapter 21], SERCA, voltage-gated Ca²⁺ channels) as the mechanism responsible for increased action potential firing: an increase in the level of cAMP (after beta-adrenergic receptor stimulation) augments the activity of protein kinase A, which then increases the rate of spontaneous SR Ca²⁺ release and SR Ca²⁺ reuptake via synergistic activation of these proteins, whereas a reduction in cAMP levels (after muscarinic receptor stimulation) has the opposite effect.¹ Acetylcholine activates K⁺ efflux through acetylcholine-sensitive inward rectifier K⁺ channels, which are expressed in both sinoatrial nodal and AV nodal cells, thereby shifting the maximum diastolic potential to more negative values. The same mechanism reduces input resistance at diastolic potentials, which means that a greater depolarizing current would be required to achieve the "threshold" for firing an action potential.

Passive Membrane Electrical Properties. Passive membrane properties, including membrane resistance, capacitance, and cable properties, play an important role in cardiac electrophysiology. Although the cardiac cell membrane is resistant to current flow, it also has capacitive properties, which means that it behaves like a battery and can store charges of opposite signs on its two sides—an excess of negative charges inside the membrane balanced by equivalent positive charges outside the membrane. These resistive and capacitive properties cause the membrane to take a certain amount of time to respond to an applied stimulus, rather than responding instantly, because the charges across the capacitive membrane must be altered first. A subthreshold rectangular current pulse applied to the membrane produces a slowly rising and decaying change in membrane voltage rather than a rectangular voltage change. A value called the time constant of the membrane reflects this property. The time

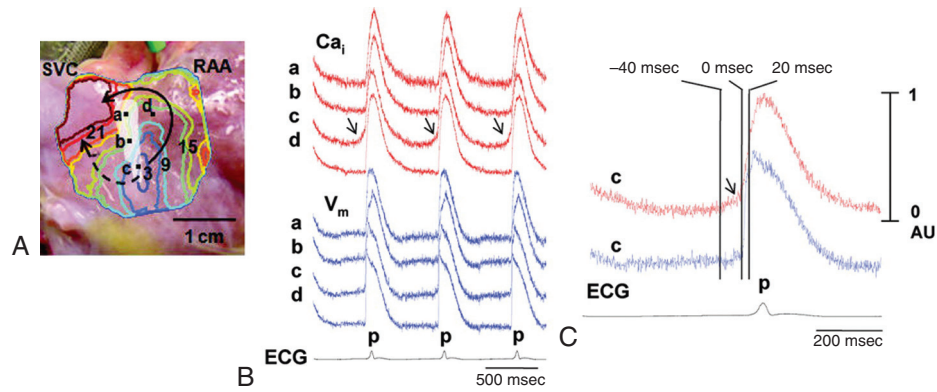

FIGURE e33-6 Demonstration of late diastolic intracellular calcium elevations in the sinoatrial node in situ by simultaneous optical mapping of changes in intracellular calcium (Ca_i) and transmembrane voltage (V_m) in an isolated canine right atrial preparation. **A**, Isochronal map of atrial activation during sinus rhythm superimposed on a photograph of the endocardial surface of the sinoatrial node region. The number on each isochronal line indicates the time of activation in milliseconds. The white shaded area is the sinoatrial node. SVC = superior vena cava; RAA = right atrial appendage. **B**, V_m (blue) and Ca_i (red) recordings from the superior (a), middle (b), and inferior (c) sinoatrial node and right atrium (d). Arrows indicate late diastolic elevations in Ca_i . Note the presence of slow diastolic depolarization in the V_m tracings a through c, but not in d. **C**, Magnified views of Ca_i and V_m tracings of the inferior sinoatrial node. The late diastolic elevation in Ca_i (arrow) precedes rapid upstroke of the sinoatrial and atrial action potential and occurs much earlier than the P wave on the electrocardiogram (ECG). (From Joung B, Tang L, Maryuama M, et al: Intracellular calcium dynamics and acceleration of sinus rhythm by β -adrenergic stimulation. *Circulation* 119:788, 2009. With permission from the American Heart Association.)

constant tau is equal to the product of membrane resistance R_m and cell capacitance C_m :

$$\tau = R_m \cdot C_m$$

This is the time taken by the membrane voltage to reach 63% of its final value after application of a steady current. The time course of changes in membrane potential after the application of a hyperpolarizing or depolarizing subthreshold current step is typically monoexponential in all myocyte types, thus indicating that the entire sarcolemma (including the T-tubular membrane; see Fig. e33-1) is charging uniformly.

When aligned end to end, cardiac cells, particularly the His-Purkinje system, behave like a long cable in which current flows more easily inside the cell and to the adjacent cell across the gap junction than it does across the cell membrane to the outside. When current is injected at a point, most of it flows along inside the cell, but some leaks out. Because of this loss of current, the change in voltage of a cell at a site distant from the point of applied current is less than the change in membrane voltage at the point where the stimulus was applied. A measure of this property of a cable is called the space or length constant lambda (λ), which is the distance along the cable from the point of stimulation at which the voltage at steady state is $1/e$ (37%) of its value at the point of introduction.

Restated, λ describes how far current flows before leaking passively across the surface membrane to a value about a third of its initial value. This distance is normally approximately 2 mm for Purkinje fibers, 0.5 mm for the sinoatrial node, and 0.8 mm for ventricular muscle fibers. λ is about 10 times the length of an individual cell. As an example, if e is approximately 2.7 and a hyperpolarizing current pulse in a Purkinje fiber produces a change in membrane voltage of 15 mV at the site of current injection, the change in membrane potential one space constant (2 mm) away would be $15/2.7 = 5.5$ mV.

Because the current loop in any circuit must be closed, current must flow back to its point of origin. Local circuit currents pass across gap junctions between cells and exit across the sarcolemmal membrane to close the loop and complete the circuit. Inward excitation currents in one area (carried by Na^+ in most regions) flow intracellularly along the length of the tissue (carried mostly by K^+), escape across the membrane, and flow extracellularly in a longitudinal direction. The outside local circuit current is the current recorded on an electrocardiogram. Through these local circuit currents the transmembrane potential of each cell influences the transmembrane potential of its neighbor because of the passive flow of current from one segment of the fiber to another across the low-resistance gap junctions.

As discussed earlier, the speed of conduction depends on active membrane properties such as the magnitude of the Na^+ current, a measure of which is \dot{V}_{max} . Passive membrane properties also contribute to conduction velocity and include the excitability threshold, which influences the capability of cells adjacent to the one that has been discharged to reach threshold; the intracellular resistance of the cell, determined by free ions in the cytoplasm; the resistance of the gap junction; and the cross-sectional area of the cell. The direction of propagation is crucial because of the influence of anisotropy, as mentioned earlier.

Loss of Membrane Potential and Development of Arrhythmia. Many acquired abnormalities of cardiac muscle or specialized fibers that result in arrhythmias produce a loss of membrane potential; that is, maximum diastolic potential becomes less negative. This change should be viewed as a symptom of an underlying abnormality, analogous to fever or jaundice, rather than as a diagnostic category in and of itself because both the ionic changes resulting in cellular depolarization and the more fundamental biochemical or metabolic abnormalities responsible for the ionic alterations probably have a number of causative factors.

Cellular depolarization can result from elevated $[\text{K}^+]_o$ or decreased $[\text{K}^+]_i$, an increase in membrane permeability to Na^+ (P_{Na} increases), or a decrease in membrane permeability to K^+ (P_{K} decreases). Reference to the GHK equation for V (see [Phases of the Cardiac Action Potential: General Considerations](#)) illustrates that these changes alone or in combination make membrane diastolic voltage less negative.

Normal cells perfused by an abnormal milieu (e.g., hyperkalemia), abnormal cells perfused by a normal milieu (e.g., healed myocardial infarction), or abnormal cells perfused by an abnormal milieu (e.g., acute myocardial ischemia and infarction) can exist alone or in combination and reduce resting membrane voltage. Each of these changes can have one or more biochemical or metabolic causes. For

example, acute myocardial ischemia results in decreased $[\text{K}^+]_i$ and increased $[\text{K}^+]_o$, release of norepinephrine, and acidosis, which may be related to an increase in intracellular Ca^{2+} and Ca^{2+} -induced transient inward currents and accumulation of amphipathic lipid metabolites and oxygen free radicals. All these changes can contribute to the development of an abnormal electrophysiologic environment and arrhythmias during ischemia and reperfusion. Knowledge of these changes may provide insight into therapy that actually reverses basic defects and restores membrane potential or other abnormalities to normal.

Effects of Reduced Resting Potential. The reduced resting membrane potential alters the depolarization and repolarization phases of the cardiac action potential. For example, partial membrane depolarization causes a decrease in the steady-state availability of fast sodium channels, thereby reducing the magnitude of peak I_{Na} during phase 0 of the action potential. The subsequent reduction in \dot{V}_{max} and action potential amplitude prolongs the conduction time of the propagated impulse, at times to the point of block.²⁸

Action potentials with reduced upstroke velocity resulting from partial inactivation of I_{Na} are called depressed fast responses (see Fig. 33-17F). Their contours often resemble and can be difficult to distinguish from slow responses, in which upstrokes are caused by I_{CaL} (see Fig. 33-17F). Membrane depolarization to levels of -60 to -70 mV can inactivate a substantial portion of the available voltage-gated Na^+ channels, and depolarization to -50 mV or less can almost completely inactivate all the Na^+ channels (see Fig. 33-12). At membrane potentials positive to -50 mV, I_{CaL} can be activated to generate phase 0 if conditions are appropriate. These changes in action potential are likely to be heterogeneous, with unequal degrees of Na^+ inactivation that create areas with minimally reduced velocity, more severely depressed zones, and areas of complete block. These uneven changes are conducive to the development of arrhythmias.

In these cells with reduced membrane potential, refractoriness can outlast voltage recovery of the action potential; that is, the cell can still be refractory or partially refractory after the resting membrane potential returns to its most negative value. Furthermore, if cardiac-impulse block occurs in a fairly localized area without significant slowing of conduction proximal to the site of block, cells in this proximal zone exhibit short action potentials and refractory periods because unexcited cells distal to the block (still in a polarized state) electrotonically speed recovery in cells proximal to the site of block.

If conduction slows gradually proximal to the site of block, the duration of these action potentials and their refractory periods can be prolonged. Some cells can exhibit abnormal electrophysiologic properties, even though they have a relatively normal resting membrane potential.

MECHANISMS OF ARRHYTHMOGENESIS

The mechanisms responsible for cardiac arrhythmias ([Table 33-4](#)) are generally divided into categories of disorders of impulse formation, disorders of impulse conduction, or combinations of both. However, our currently available diagnostic tools do not permit unequivocal determination of the electrophysiologic mechanisms responsible for many clinically occurring arrhythmias or their ionic bases. This is especially true for ventricular arrhythmias. It may be clinically difficult to separate microanatomic reentry from automaticity, and often one is left with the consideration that a particular arrhythmia is "most consistent with" or "best explained by" one or the other electrophysiologic mechanism. Some tachyarrhythmias can be started by one mechanism and be perpetuated by another. An episode of tachycardia caused by one mechanism can precipitate another episode caused by a different mechanism. For example, an initiating tachycardia or premature complex caused by abnormal automaticity can precipitate an episode of tachycardia sustained by reentry. However, by use of the features of entrainment (see later), arrhythmias caused by macroreentry circuits can be identified.

Disorders of Impulse Formation

Disorders in this category are characterized by an inappropriate discharge rate of the normal pacemaker, the sinoatrial node (e.g., sinus

TABLE 33-4 Mechanisms of Arrhythmogenesis

DISORDER	EXPERIMENTAL EXAMPLES	CLINICAL EXAMPLES
Disorders of Impulse Formation		
Automaticity		
Normal automaticity	Normal in vivo or in vitro in sinoatrial nodal, AV nodal, and Purkinje cells	Sinus tachycardia or bradycardia inappropriate for the clinical situation; possibly ventricular parasystole
Abnormal automaticity	Depolarization-induced automaticity in Purkinje myocytes	Possibly accelerated ventricular rhythms after myocardial infarction
Triggered activity		
EADs	Drugs (sotalolol, <i>N</i> -acetylprocainamide, terfenadine, erythromycin), cesium, barium, low $[K^+]_o$	Acquired LQTS and associated ventricular arrhythmias
DADs	Gain-of-function mutations in the gene encoding RyR2	Catecholaminergic polymorphic ventricular tachycardia
Disorders of Impulse Conduction		
Block		
Bidirectional or unidirectional without reentry	Sinoatrial, AV, bundle branch, Purkinje-muscle	Sinoatrial, AV, bundle branch block
Unidirectional block with reentry	AV node, Purkinje-muscle junction, infarcted myocardium	Reciprocating tachycardia in Wolff-Parkinson-White syndrome, AV nodal reentry tachycardia, ventricular tachycardia caused by bundle branch reentry
Reflection	Purkinje fiber with area of inexcitability	Unknown
Combined Disorders		
Interactions between automatic foci	Depolarizing or hyperpolarizing subthreshold stimuli speed or slow the automatic discharge rate	Modulated parasystole
Interactions between automaticity and conduction	Deceleration-dependent block, overdrive suppression of conduction, entrance and exit block	Similar to experimental

rates too fast or too slow for the physiologic needs of the patient), or discharge of an ectopic pacemaker that controls atrial or ventricular rhythm. Pacemaker discharge from ectopic sites, often called latent or subsidiary pacemakers, can occur in fibers located in several parts of the atria, coronary sinus and pulmonary veins, AV valves, portions of the AV junction, and His-Purkinje system. Ordinarily kept from reaching the level of threshold potential because of overdrive suppression by the more rapidly firing sinus node or electrotonic depression from contiguous fibers, ectopic pacemaker activity at one of these latent sites can become manifested when the sinus nodal discharge rate slows or block occurs at some level between the sinoatrial node and the ectopic pacemaker site, which permits *escape* of the latent pacemaker at the latter's normal discharge rate. A clinical example would be sinus bradycardia to a rate of 45 beats/min that permits an AV junctional escape complex to occur at a rate of 50 beats/min.

Alternatively, the discharge rate of the latent pacemaker can speed inappropriately and usurp control of cardiac rhythm from the sinoatrial node, which has been discharging at a normal rate, such as occurs with a premature ventricular complex (PVC) or a burst of ventricular tachycardia. Such disorders of impulse formation can be caused by speeding or slowing of a *normal* pacemaker mechanism (e.g., phase 4 diastolic depolarization that is ionically normal for the sinoatrial node or for an ectopic site such as a Purkinje fiber but occurs inappropriately fast or slow) or by an ionically *abnormal* pacemaker mechanism.

A patient with persistent sinus tachycardia at rest or sinus bradycardia during exertion exhibits inappropriate sinus nodal discharge rates, but the ionic mechanisms responsible for sinus nodal discharge can still be normal, although the kinetics or magnitude of the currents can be altered. Conversely, when a patient experiences ventricular tachycardia during acute myocardial infarction, ionic mechanisms ordinarily not involved in the formation of spontaneous impulses for this fiber type can be operative and generate the tachycardia. For example, although pacemaker activity is not generally found in ordinary working myocardium, the effects of myocardial infarction can perhaps depolarize these cells to membrane potentials

at which inactivation of I_K and activation of $I_{Ca,L}$ cause automatic discharge. In vitro studies have demonstrated that myofibroblasts in infarct scars depolarize cardiomyocytes by heterocellular electrotonic interactions via gap junctions and also induce synchronized spontaneous activity in neighboring cardiomyocytes.⁶⁶

Abnormal Automaticity. The mechanisms responsible for normal automaticity were described earlier. Abnormal automaticity can arise from cells that have reduced maximum diastolic potentials, often at membrane potentials positive to -50 mV, when I_K and $I_{Ca,L}$ may be operative.

Automaticity at membrane potentials more negative than -70 mV may be caused by I_f . When the membrane potential is between -50 and -70 mV, the cell may be quiescent. Electrotonic effects from surrounding normally polarized or more depolarized myocardium influence the development of automaticity.⁶⁴ Abnormal automaticity has been found in Purkinje fibers removed from dogs subjected to myocardial infarction, in rat myocardium damaged by epinephrine, in human atrial samples, and in ventricular myocardial specimens from patients undergoing aneurysmectomy and endocardial resection for recurrent ventricular tachyarrhythmias.

Abnormal automaticity can be produced in normal muscle or Purkinje fibers by appropriate interventions, such as passage of current that reduces diastolic potential. An automatic discharge rate speeds up with progressive depolarization, and hyperpolarizing pulses slow the spontaneous firing. It is possible that partial depolarization and failure to reach normal maximal diastolic potential can induce automatic discharge in most if not all cardiac fibers. Although this type of spontaneous automatic activity has been found in human atrial and ventricular fibers, its relationship to the genesis of clinical arrhythmias has not been established. Abnormal automaticity in Purkinje cells can also originate secondary to spontaneous, submembrane Ca^{2+} elevations via activation of calcium-sensitive membrane conductances, a process identical to that previously identified in sinoatrial nodal myocytes. Indeed, Purkinje myocytes isolated from mice heterozygous for an arrhythmia-causing mutation in the gene encoding the cardiac ryanodine receptor Ca^{2+} release channel (RyR2) display a greater propensity for the development of arrhythmogenic Ca^{2+} -handling abnormalities than do mutant ventricular cardiomyocytes.⁶⁷ This proarrhythmic behavior is further exacerbated by catecholaminergic

FIGURE 33-19 Polymorphic ventricular tachycardia and sudden death in an animal model of type 4 LQTS. **A**, Electrocardiogram after exercise and administration of epinephrine in a mouse heterozygous for a loss-of-function mutation in the gene encoding ankyrin-B ($AnkB^{+/-}$). Polymorphic ventricular tachycardia (torsades de pointes) occurred within about 17 minutes of epinephrine administration, followed by marked bradycardia and death 2 minutes after the arrhythmia. **B**, Transmembrane action potentials in single cardiomyocytes from $AnkB^{+/-}$ mice at the frequencies indicated. Acute exposure to isoproterenol induced both DADs and EADs, which led to extra beats. (From Mohler PJ, Schott J, Gramolini AO, et al: Ankyrin-B mutation causes type 4 long-QT cardiac arrhythmia and sudden cardiac death. *Nature* 421:634, 2003.)

stimulation with the development of triggered beats (Fig. e33-7), thus supporting the concept that Purkinje cells are critical contributors to arrhythmic triggers in animal models and humans with RyR2 mutations that are linked to CPVT. The occurrence of such spontaneous localized $[Ca^{2+}]_i$ transients has been confirmed in canine Purkinje cells (see Video 33-2).⁶⁸

Rhythms resulting from automaticity may be slow atrial, junctional, and ventricular escape rhythms; certain types of atrial tachycardias (e.g., those produced by digitalis or perhaps those coming from pulmonary veins); accelerated junctional (nonparoxysmal junctional tachycardia) and idioventricular rhythms; and parasystole (see Chapter 37).

Triggered Activity

Automaticity is the property of a fiber to initiate an impulse spontaneously, without need for prior stimulation, so that electrical quiescence does not occur. Triggered activity is initiated by afterdepolarizations, which are depolarizing oscillations in membrane voltage induced by one or more preceding action potentials. Thus triggered activity is pacemaker activity that results as a consequence of a preceding impulse or series of impulses, without which electrical quiescence occurs (Fig. 33-19). This triggering activity is not caused by an automatic self-generating mechanism, and the term *triggered automaticity* is therefore contradictory. These depolarizations can occur before or after full repolarization of the fiber and are best termed EADs when they arise from a reduced level of membrane potential during phases 2 (type 1) and 3 (type 2) of the cardiac action potential (see

Fig. e33-12) or late afterdepolarizations or DADs (see Fig. 33-19) when they occur after completion of repolarization (phase 4), generally at a more negative membrane potential than that from which EADs arise. Not all afterdepolarizations may reach threshold potential, but if they do, they can trigger another afterdepolarization and thus self-perpetuate.

Delayed Afterdepolarizations. DADs and triggered activity have been demonstrated in Purkinje fibers, specialized atrial fibers and ventricular muscle fibers exposed to digitalis preparations, pulmonary veins, normal Purkinje fibers exposed to Na-free superfusates from the endocardium of the intact heart, ventricular myocardial cells from failing hearts (Fig. 33-20) and from mouse hearts with ankyrin-B mutations (see Fig. 33-19) during beta-adrenergic stimulation, and endocardial preparations 1 day after a myocardial infarction.^{69,70} When fibers in the rabbit, canine, simian, and human mitral valves and in the canine tricuspid valve and coronary sinus are superfused with norepinephrine, they exhibit the capability for sustained triggered rhythmic activity.

Triggered activity caused by DADs has also been noted in diseased human atrial and ventricular fibers studied in vitro. Left stellate ganglion stimulation can elicit DADs in canine ventricles. In vivo, atrial and ventricular arrhythmias apparently caused by triggered activity have been reported in the dog and possibly in humans. It is tempting to ascribe certain clinical arrhythmias to DADs, such as some arrhythmias precipitated by digitalis or some cases of AF arising from DADs in pulmonary veins. The accelerated idioventricular rhythm 1 day after experimental canine myocardial infarction may be caused by DADs, and some evidence has suggested that certain ventricular tachycardias, such as those arising in the right ventricular outflow tract, may be caused by DADs, whereas other data suggest that EADs are responsible.⁷¹

Major Role of Intracellular Ca^{2+} -Handling Abnormalities in the Generation of Delayed Afterdepolarizations. It is well recognized that DADs result from the activation of a calcium-sensitive inward current elicited by spontaneous increases in the intracellular free calcium concentration. Acquired or inherited abnormalities in the properties of the SR calcium release channels or SR calcium-binding proteins underlie these spontaneous calcium release events.

Rapid mobilization of Ca^{2+} from the SR into the cytosol is mediated by the synchronous opening of ryanodine-sensitive Ca^{2+} release channels (ryanodine receptors, RyRs). The cardiac RyR is composed of four equivalent subunits (homotetramer), each encoded by the *RYR2* gene. During cardiac systole, the small influx of calcium ions through L-type Cav channels triggers a massive release of Ca^{2+} from the SR via synchronous opening of RyR2 channels, a process called Ca^{2+} -induced Ca^{2+} release (see Chapter 21). During diastole, RyR2 channels close and Ca^{2+} is recycled into the SR via calcium pumps, thereby refilling SR Ca^{2+} stores for the next release cycle. The duration and amplitude of Ca^{2+} efflux from the SR are therefore tightly controlled by the gating of RyR2 channels. RyR2 interacts with a number of accessory proteins to form a macromolecular Ca^{2+} release complex (see Fig. e33-6). Proteins interact with RyR2 at multiple sites within the cytosolic domains of RyR2 (e.g., protein phosphatases) or at the SR level (e.g., calsequestrin, the major calcium-binding protein in the SR lumen). Among the cytosolic ligands, FKBP-12.6 (calstabin 2) has been implicated in stabilizing the closed state of the RyR2 channel and thus preventing diastolic Ca^{2+} leakage (Fig. e33-8).⁷²

Mutations in the human *RYR2* gene and in the gene *CASQ2*, which encodes calsequestrin (see Fig. e33-6), have been linked to CPVT. Experimental studies have revealed that the *RYR2* and *CASQ2* mutations that underlie CPVT cause an increase in the sensitivity of the RyR2 channel to luminal Ca^{2+} activation on adrenergic stimulation (e.g., from emotional or physical stress) and enhance the propensity for spontaneous, diastolic Ca^{2+} release from the SR and subsequent DAD-triggered arrhythmias (see later).^{27,73-75} It is also possible that CPVT mutants exhibit reduced affinity for binding of the regulatory protein FKBP-12.6, thereby resulting in diastolic Ca^{2+} leakage from the SR.⁷⁶ Reduced FKBP-12.6 binding caused by protein kinase A-mediated hyperphosphorylation has been implicated in cardiac arrhythmogenesis associated with heart failure.⁷⁷ Polymorphic

FIGURE e33-7 Arrhythmogenic spontaneous Ca^{2+} elevations in a Purkinje myocyte isolated from a mouse heterozygous for a gain-of-function mutation in the *RYR2* gene. Changes in intracellular free calcium ($\Delta[\text{Ca}^{2+}]_i$, upper trace) and transmembrane action potential (V_m) were simultaneously recorded in a mutant Purkinje myocyte during electrical field stimulation (arrows) and during a spontaneous elevation in Ca^{2+} (triggered action potential, TA). Note that the action potential upstroke is preceded by a low-amplitude elevation in Ca^{2+} , followed by a suprathreshold membrane depolarization that triggers a markedly prolonged action potential. (From Kang G, Giovannone SF, Liu N, et al: Purkinje cells from *RyR2* mutant mice are highly arrhythmogenic but responsive to targeted therapy. *Circ Res* 107:512, 2010.)

VIDEO 33-2

Trigger of whole-cell Ca^{2+} waves by subsarcolemmal Ca^{2+} events. Images were taken from a Purkinje cell region covering sarcolemma, subsarcolemmal space, and a small area of the cell-center. The cell was loaded with the calcium-sensitive dye fluo-4. Changes in $[\text{Ca}^{2+}]_i$ were color-coded, with red and white indicating high and low $[\text{Ca}^{2+}]_i$ levels, respectively. Two types of Ca^{2+} events are demonstrated: spontaneous elevations that are confined to a $\sim 6\text{-mm}$ wide region under the outer membrane (wavelet), and wavelets that initiate waves that propagate to the cell-center. (From Stuyvers BD, Dun W, Matkovich S, et al: Ca^{2+} sparks and waves in canine Purkinje cells. *Circ Res* 97:35, 2005.)

CaM = calmodulin; CaMKII = calmodulin-dependent kinase II; FKBP = FK506 binding protein 12.6; PKA = protein kinase A; PP = protein phosphatase. Calsequestrin, junctin, and triadin are proteins that interact with RyR2 in the SR. (From Bers DM: Macromolecular complexes regulating cardiac ryanodine receptor function. *J Mol Cell Cardiol* 37:417, 2004.)

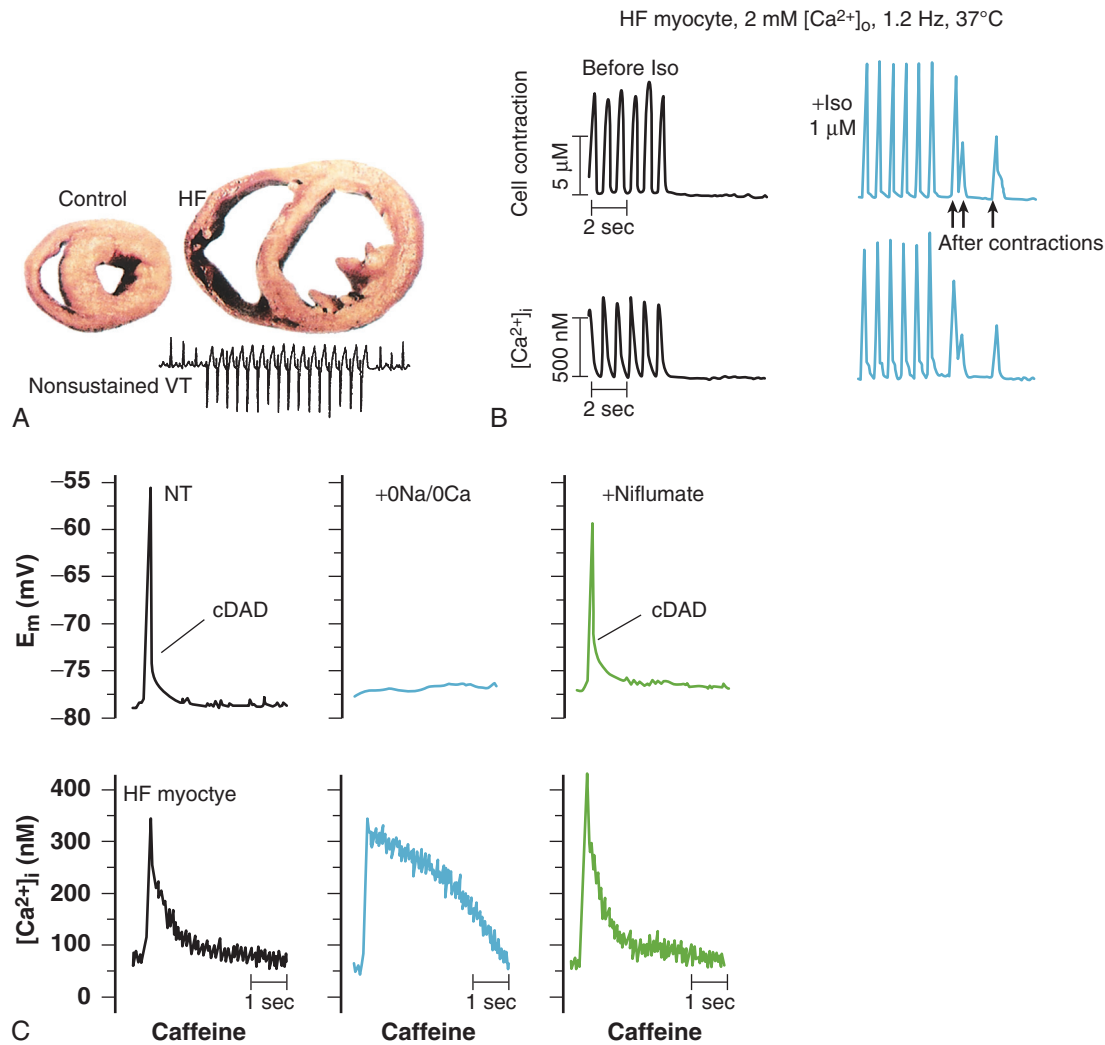

FIGURE 33-20 Ventricular arrhythmia in an animal model of heart failure (aortic constriction-insufficiency in the rabbit). **A**, Cross sections of a control and failing heart (HF) and Holter recording of nonsustained ventricular tachycardia (VT) seen in a failing heart. **B**, Spontaneous aftercontractions and increases in $[Ca^{2+}]_i$ in a failing cardiomyocyte after exposure to isoproterenol. **C**, Induction of a DAD by the application of caffeine (cDAD) in a cardiomyocyte isolated from a failing rabbit heart. In normal Tyrode (NT) solution, caffeine causes rapid release of Ca^{2+} from the SR, thereby leading to increases in the intracellular free calcium concentration (bottom tracing), which in turn causes membrane depolarization. Blocking of the Na^+/Ca^{2+} exchange current in Na^+ -free and Ca^{2+} -free solution (0Na/0Ca) abolished DADs despite a similar increase in $[Ca^{2+}]_i$, whereas blocking of the Ca^{2+} -activated Cl^- current with niflumate did not prevent DADs. E_m = membrane voltage. (From Pogwizd SM, Schlotthauer K, Li L, et al: Arrhythmogenesis and contractile dysfunction in heart failure. *Circ Res* 88:1159, 2001. By permission of the American Heart Association.)

ventricular tachycardia develops in FKBP-12.6-deficient mice on adrenergic stimulation.⁷⁸ Treatment with the 1,4-benzothiazepine derivatives JTV519 and S107, which restore FKBP-12.6 affinity for RyR2, has been shown to suppress catecholamine-induced polymorphic ventricular tachycardia in FKBP-12.6-deficient mice.^{27,79}

The IP_3 receptor (IP_3R) is another Ca^{2+} release channel in cardiomyocytes that is activated by binding of the second messenger IP_3 and cytosolic Ca^{2+} . IP_3R exists as a homotetramer or heterotetramer, each encoded by the *ITPR1*, *ITPR2*, or *ITPR3* gene (Fig. e33-9). The type 2 IP_3R is the predominant subtype in atrial myocytes, where they are located near RyR2 channels at the SR Ca^{2+} release sites and contribute to altered excitation-contraction coupling and arrhythmogenesis in the atria.⁸⁰ In Purkinje myocytes, type 1 IP_3R s colocalize with type 3 RyR in the subsarcolemmal space to form a functional dyad that critically determines electrical excitability.^{68,81} IP_3 -dependent Ca^{2+} signaling has been implicated in cardiac arrhythmias attributable to ischemia and reperfusion injury, inflammatory processes, and developing cardiac failure.⁸² IP_3R s are upregulated in heart failure and AF.⁸³ In atrial and Purkinje myocytes, IP_3 causes spontaneous $[Ca^{2+}]_i$ transients, Ca^{2+} waves, and Ca^{2+} alternans and facilitates the generation of afterdepolarizations.⁸²

The cascade of events linking cellular Ca^{2+} -handling abnormalities to cardiac arrhythmias is illustrated in Figure 33-21. Ca^{2+} leaking through SR Ca^{2+} release channels during diastole gives rise to localized increases in the cytosolic calcium level in a single cardiomyocyte. The

focally elevated Ca^{2+} then causes a propagating Ca^{2+} wave that depolarizes the cardiomyocyte membrane and triggers a DAD via transient activation of the inward Na^+/Ca^{2+} exchange current ($I_{Na/Ca}$).⁵² Inhibition of calmodulin kinase eliminates transient inward $I_{Na/Ca}$ in isolated rabbit ventricular myocytes, thus indicating that activation of this enzyme plays an important role in cardiac arrhythmogenesis. In addition, drugs that reduce I_{Na} also reduce the transient inward current, relieve Ca^{2+} overload, and can abolish DADs. DADs most likely play a causative role in arrhythmogenesis in the failing heart, where upregulation of $I_{Na/Ca}$, in combination with downregulation of the inward rectifier K^+ current I_{K1} , facilitates DAD generation (see Fig. 33-20).⁵²

Although a causal role of spontaneous SR Ca^{2+} release events in triggering DADs in isolated cardiomyocytes is generally accepted, little is known about whether or how calcium waves within the heart actually produce arrhythmogenic membrane depolarizations. A study using simultaneous optical mapping of changes in $[Ca^{2+}]_i$ and membrane potential with cellular resolution in the intact, isolated perfused rat heart demonstrated that the occurrence of triggered activity requires the synchronous appearance of Ca^{2+} waves in multiple, adjacent cardiomyocytes. In contrast, sporadic Ca^{2+} waves in individual cardiomyocytes never gave rise to triggered activity (Fig. e33-10).⁸⁴

A recent dual-voltage (V_m) and Ca^{2+} optical mapping study similarly investigated the mechanism by which Ca^{2+} -induced DADs are synchronized in the myocardium in response to beta-adrenergic receptor

FIGURE e33-9 Structure of the IP₃ receptor (IP₃R). IP₃Rs are intracellular membrane proteins that exist as homotetramers or heterotetramers. The Ca²⁺ conducting pore is believed to be created at the central axis of the tetrameric structure. The cartoon depicts three of four IP₃R molecules (in different colors) in a single tetrameric channel structure. Part of the luminal loop (i.e., the loop facing the SR lumen) connecting transmembrane helices 5 and 6 of each monomer dips into the fourfold symmetrical axis and creates the pathway for efflux of Ca²⁺ from the SR lumen. (From Foskett JK, White C, Cheung KH, et al: Inositol trisphosphate receptor Ca²⁺ release channels. *Physiol Rev* 87:593, 2007.)

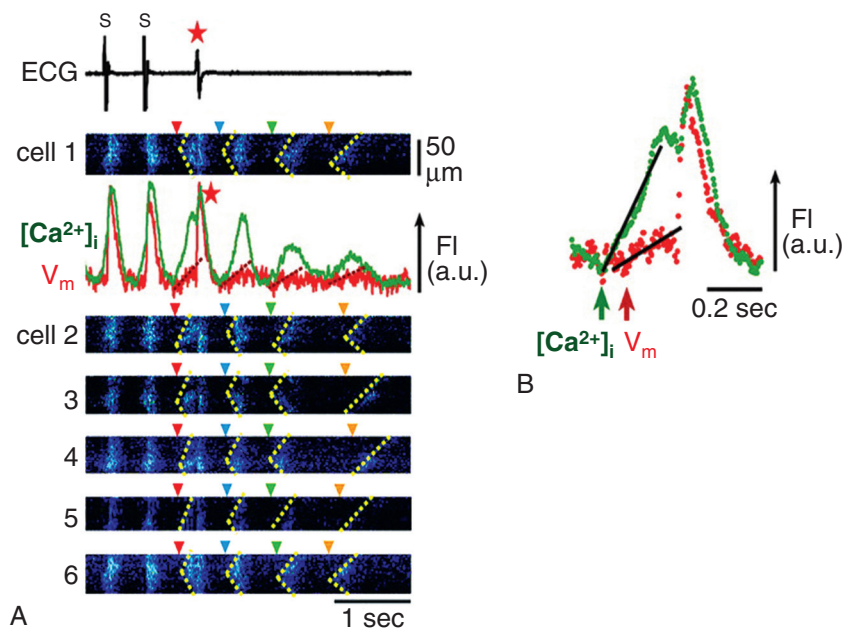

FIGURE e33-10 Triggered activity mediated by Ca²⁺ waves in an intact rat heart. **A**, Synchronous emergence of Ca²⁺ waves (dotted lines) in individual cells (1 through 6) accompanies a single event of triggered activity (red asterisk), followed by Ca²⁺ oscillations (green trace), with concomitant membrane fluctuations (red trace) showing a gradual reduction in amplitude. Only the first Ca²⁺ wave (red arrowhead), not the following three, triggers a propagating impulse. Fluorescence intensities of the calcium- and voltage-sensitive dyes fluo-4 and RH237, respectively, were measured in adjacent subepicardial ventricular myocytes within a Langendorff-perfused rat heart with dual-view, rapid scanning confocal microscopy. The triggered activity was induced by 2-Hz pacing under low K⁺ (2.4 mmol/L) perfusion and isoproterenol (3 nmol/L). **B**, Simultaneous V_m and intracellular Ca²⁺ recordings during the triggered beat demarcated by the red arrowhead in **A** at an expanded time scale demonstrate that the increase in [Ca²⁺]_i precedes membrane depolarization. FI = fluorescence intensity. (Modified from Fujiwara K, Tanaka H, Mani H, et al: Burst emergence of intracellular Ca²⁺ waves evokes arrhythmogenic oscillatory depolarization via the Na⁺-Ca²⁺ exchanger. *Circ Res* 103:509, 2008. With permission from the American Heart Association.)

FIGURE 33-21 Proposed scheme of events leading to DADs and triggered tachyarrhythmia. **Top panel**, Congenital (e.g., gain-of-function mutations in the *RYR2* or *CASQ2* genes) or acquired factors (e.g., ischemia, hypertrophy, increased sympathetic tone, heart failure) will cause a diastolic Ca^{2+} leak through RyR2 that results in localized and transient increases in $[\text{Ca}^{2+}]$ in cardiomyocytes. **Middle panel**, Representative series of images showing changes in $[\text{Ca}^{2+}]$ during a Ca^{2+} wave in a single cardiomyocyte loaded with a Ca^{2+} -sensitive fluorescent dye. Images were obtained at 117-millisecond intervals. Focally elevated Ca^{2+} (2) diffuses to the adjacent junctional SR, where it initiates more Ca^{2+} release events that result in a propagating Ca^{2+} wave (3 to 8). **Bottom panel**, The Ca^{2+} wave, through activation of inward $I_{\text{Na/Ca}}$, will depolarize the cardiomyocyte (DAD). If of sufficient magnitude to overcome the source-sink mismatch, the DAD will depolarize the cardiomyocyte above threshold and result in a single or repetitive premature heartbeat (red arrows), which can trigger an arrhythmia. Downregulation of the inwardly rectifying potassium current (I_{K1}), upregulation of $I_{\text{Na/Ca}}$, and shortened Ca^{2+} signaling refractoriness because of ryanodine receptor phosphorylation and/or oxidation can promote the generation of DAD-triggered action potentials. S = stimulus. (Modified from Rubart M, Zipes DP: Mechanisms of sudden cardiac death. *J Clin Invest* 115:2305, 2005. With permission from the Journal of Clinical Investigation.)

stimulation to overcome the source-sink mismatch and generate focal arrhythmias.⁸⁵ In this study, local intramyocardial injection of the sympathetic neurotransmitter norepinephrine was used to induce triggered arrhythmias. Spatial patterns of V_m - Ca^{2+} delay during norepinephrine-induced PVCs were compared with sinus rhythm, ventricular pacing, and normal Tyrode solution-induced PVCs, as shown in **Figure e33-11**.

Another study involving isolated left ventricular cardiomyocytes from failing canine hearts suggested shortened Ca^{2+} signaling refractoriness because of altered post-translational modification of the ryanodine receptor Ca^{2+} release channel as a mechanism responsible for the increased incidence of diastolic Ca^{2+} waves associated with this disease and could provide an additional substrate for synchronization of arrhythmogenic events at the tissue level in hearts prone to VF.⁸⁶

Short coupling intervals and pacing at rates more rapid than the triggered activity rate (overdrive pacing) increase the amplitude and shorten the cycle length of the DAD after cessation of pacing (overdrive acceleration) rather than suppressing and delaying the escape rate of the afterdepolarization, as in normal automatic mechanisms. Premature stimulation exerts a similar effect: the shorter the premature interval, the larger the amplitude and the shorter the escape interval of the triggered event.

The clinical implication might be that tachyarrhythmias caused by DAD-triggered activity may not be suppressed easily or indeed may be precipitated by rapid rates, either spontaneously (such as with sinus tachycardia) or induced by pacing. Finally, because a single premature stimulus can both initiate and terminate triggered activity, differentiation from reentry (see later) becomes difficult. The response to overdrive pacing may help separate triggered arrhythmias from reentrant arrhythmias.

Early Afterdepolarizations

Various interventions, each of which results in an increase in intracellular positivity, can cause EADs. EADs may be responsible for the lengthened repolarization time and ventricular tachyarrhythmias seen in several clinical situations, such as the acquired and congenital forms of LQTS (see **Fig. 33-19**; see **Chapter 37**).⁸⁷ Left ansa subclavian stimulation increases the amplitude of cesium-induced EADs in dogs and the prevalence of ventricular tachyarrhythmias more than right ansa subclavian stimulation does, possibly because of a greater quantitative effect of the left than of the right stellate ganglion on the left ventricle.

Long-QT Syndrome

Patients with heritable LQTS have an abnormally prolonged cardiac action potential duration and are at increased risk for sudden cardiac death from ventricular tachyarrhythmias (see **Chapters 32 and 37**). The genesis of LQTS-associated ventricular tachycardia or fibrillation is uncertain. Evidence

is mounting that an increased intracellular Ca^{2+} concentration related to spontaneous release of Ca^{2+} from the SR in cardiomyocytes, coupled with dispersion of repolarization, plays a causative role in LQTS-associated cardiac arrhythmia and sudden cardiac death. Action potential prolongation may increase influx of Ca^{2+} through L-type Ca^{2+} channels during a cardiac cycle and cause excessive accumulation of Ca^{2+} in the SR and spontaneous release of Ca^{2+} from the SR. The ensuing elevation of intracellular free calcium can depolarize cardiomyocyte membrane potential by activation of Ca^{2+} -dependent chloride currents, the electrogenic $\text{Na}^+/\text{Ca}^{2+}$ exchange current, or both, thereby evoking EADs. EADs can trigger a propagated response and thus elicit an extra beat, which can potentially launch a tachycardia.

Genetically modified mice have been used extensively to model congenital arrhythmogenic disorders, including LQTS. However, the

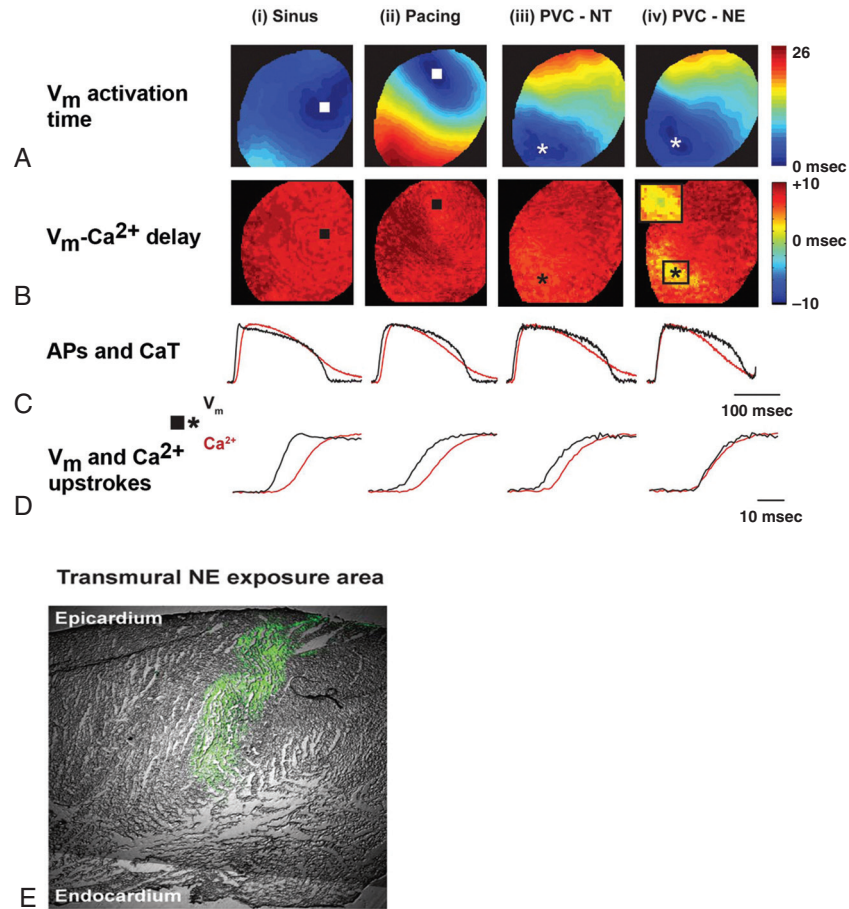

FIGURE e33-11 Ca^{2+} -induced triggered activity in the rabbit heart. **A, B,** Color-coded isochrone maps of transmembrane voltage (V_m) activation (**A**) and delay between V_m and Ca^{2+} upstroke (V_m - Ca^{2+} delay; **B**) in an isolated perfused rabbit heart during (i) sinus rhythm, (ii) ventricular pacing, (iii) normal Tyrode solution (NT)-induced PVC, and (iv) norepinephrine (NE)-induced PVC. Color codes are shown on the right. During sinus rhythm, ventricular pacing, and NT-induced PVCs, Ca^{2+} activation followed V_m with a relatively uniform delay across the epicardial surface (**B**, i-iii); however, during NE-induced PVCs, areas of abnormally short V_m - Ca^{2+} delays (iv) were seen at the site of earliest V_m activation, thus suggesting that beta-adrenergically mediated SR Ca^{2+} release events were of sufficient magnitude to cause a propagating action potential via activation of the Na/Ca exchanger. **C,** Optical action potentials (APs; black) and Ca^{2+} transients (CaTs; red) from the earliest activated sites. **D,** V_m and Ca^{2+} upstrokes from the earliest activated sites. **E,** Transmural section of the left ventricle showing the area of NE distribution (green) following its direct intracardiac injection. (From Myles RC, Wang L, Kang C, et al: Local α -adrenergic stimulation overcomes source-sink mismatch to generate focal arrhythmia. *Circ Res* 110:1454, 2012.)

usefulness of this approach is limited because of the profound differences in electrophysiologic properties between the murine and human heart. The ability to generate patient-specific human iPSCs offers a new paradigm for modeling human disease. Recently, several research groups have independently reported successful derivation of functional cardiomyocytes from LQTS patient-specific human iPSC lines. Electrophysiologic evaluation of LQTS cardiomyocytes demonstrated that they recapitulate the disease phenotype in vitro, including marked action potential prolongation and increased susceptibility to spontaneous or pharmacologically induced triggered activity.^{88,89} An example of such a study in cardiomyocytes derived from LQTS patient-specific iPSCs is summarized in **Figure e33-12**.

Large-scale production of human iPSC-derived cardiomyocytes has made it possible to generate sufficient numbers of uniform cardiac monolayers that can be used for the study of arrhythmia mechanisms in vitro.⁹⁰ Collectively, pluripotent stem cell technology now offers a unique platform to evaluate patient-specific arrhythmia mechanisms and to optimize patient therapy.

Experimental observations have also suggested an important role of transmural or longitudinal heterogeneity of repolarization. Marked transmural dispersion of repolarization can create a vulnerable window for the development of reentry. Direct experimental evidence of the existence of transmural dispersion in the action potential has been provided for the human heart.⁹¹ Optical voltage mapping of arterially perfused wedges from human hearts revealed significant transmural action potential gradients in the nonfailing heart ranging from a mean of 383 milliseconds (action potential duration at 80% repolarization) in the subepicardium to a mean of 494 milliseconds in the endocardium. Three of five hearts studied showed midmyocardial islands of cells that had distinctly long action potential durations averaging 537 milliseconds and a steep local action potential duration gradient of 27 msec/mm. In contrast, failing hearts were observed to have a significantly reduced transmural gradient averaging 29 milliseconds and to lack islands of cells with delayed repolarization. The ionic mechanisms underlying transmural dispersion of repolarization in the human heart are currently unknown but may involve spatial variations in expression of the transient outward potassium current I_{to} and the delayed rectifying potassium current I_{Kr} (see **Table 33-3**).

Sympathetic stimulation, primarily left, can increase the EAD amplitude to provoke ventricular tachyarrhythmias. Alpha-adrenoceptor stimulation also increases the amplitude of cesium-induced EADs and the prevalence of ventricular tachyarrhythmias, both of which are suppressed by magnesium.

In patients with acquired LQTS and torsades de pointes from drugs such as quinidine, *N*-acetylprocainamide, cisapride, erythromycin, and some class III antiarrhythmic agents, EADs can also be responsible (see **Chapters 9 and 35**). Such drugs easily elicit EADs experimentally and clinically, whereas magnesium suppresses them. It is possible that multiple drugs can cause summation effects to provoke EADs and torsades de pointes in patients. Activators of ATP-dependent potassium channels, such as pinacidil and nicorandil, can eliminate EADs.

Parasystole

Classically, parasystole has been likened to the function of a fixed-rate, asynchronously discharging pacemaker—its timing is not altered by the dominant rhythm, it produces depolarization when the myocardium is excitable, and the intervals between discharges are multiples of a basic interval (see **Chapters 36 and 37**). Complete entrance block, constant or intermittent, insulates and protects the parasystolic focus from surrounding electrical events and accounts for such behavior. On occasion, the focus can exhibit exit block, during which it may fail to depolarize excitable myocardium. In fact, the dominant cardiac rhythm may modulate parasystolic discharge to speed up or to slow down its rate. Brief subthreshold depolarizations induced during the first half of the cardiac cycle of a spontaneously discharging pacemaker delay the subsequent discharge, whereas similar depolarizations induced in the second half of the cardiac cycle accelerate it (**Fig. e33-13**).

Disorders of Impulse Conduction

Conduction delay and block can result in bradyarrhythmias or tachyarrhythmias. Bradyarrhythmias occur when the propagating impulse is blocked and is followed by asystole or a slow escape rhythm; tachyarrhythmias occur when the delay and block produce reentrant excitation (see later). Various factors involving both active and passive membrane properties determine the conduction velocity of an impulse and whether conduction is successful. Among these factors are the stimulating efficacy of the propagating impulse, which is related to the amplitude and rate of rise of phase 0; the excitability of the tissue into which the impulse is conducted; and the geometry of the tissue.

Deceleration-Dependent Block

Diastolic depolarization has been suggested as a cause of conduction block at slow rates, so-called bradycardia- or deceleration-dependent block (see **Chapter 37**). However, excitability and the speed of impulse propagation *increase* as the membrane depolarizes until approximately -70 mV despite a reduction in action potential amplitude and \dot{V}_{max} (supernormal conduction). Experiments in Purkinje fiber bundles have demonstrated that diastolic (phase 4) depolarization is not a necessary condition for the occurrence of deceleration-dependent block.⁹² Evidently, depolarization-induced inactivation of fast Na^+ channels is offset by other factors, such as a reduction in the difference between membrane potential and threshold potential and an increase in membrane excitability.

Tachycardia-Dependent Block

More commonly, impulses are blocked at rapid rates or short cycle lengths as a result of incomplete recovery of refractoriness (postrepolarization refractoriness) caused by incomplete time- or voltage-dependent recovery of excitability.⁹³ For example, such incomplete recovery is the usual mechanism responsible for a nonconducted premature P wave or one that conducts with a functional bundle branch block.

Decremental Conduction

Decremental conduction is a term used commonly in the clinical literature but is often misapplied to describe any Wenckebach-like conduction block, that is, responses similar to a block in the AV node during which progressive conduction delay precedes the nonconducted impulse. Correctly used, decremental conduction refers to a situation in which the properties of the fiber change along its length such that the action potential loses its efficacy as a stimulus to excite the fiber ahead of it. Thus the stimulating efficacy of the propagating action potential diminishes progressively, possibly as a result of its decreasing amplitude and decreasing \dot{V}_{max} .

Reentry

Electrical activity during each normal cardiac cycle begins in the sinoatrial node and continues until the entire heart has been activated. Each cell becomes activated in turn, and the cardiac impulse dies out when all fibers have been discharged and are completely refractory. During this absolute refractory period, the cardiac impulse has “no place to go.” It must be extinguished and restarted by the next sinus impulse. If, however, a group of fibers not activated during the initial wave of depolarization recovers excitability in time to be discharged before the impulse dies out, the fibers may serve as a link to reexcite areas that were just discharged and have now recovered from the initial depolarization. Such a process has been given various names—reentry, reentrant excitation, circus movement, reciprocal or echo beat, or reciprocating tachycardia—all meaning approximately the same thing.

Entrainment

Entraining the tachycardia (i.e., increasing the rate of the tachycardia by pacing), with resumption of the intrinsic rate of the tachycardia when pacing is stopped, establishes the presence of reentry (**Fig. 33-22A**). Entrainment represents capture or continuous resetting of the reentrant circuit of the tachycardia by the pacing-induced

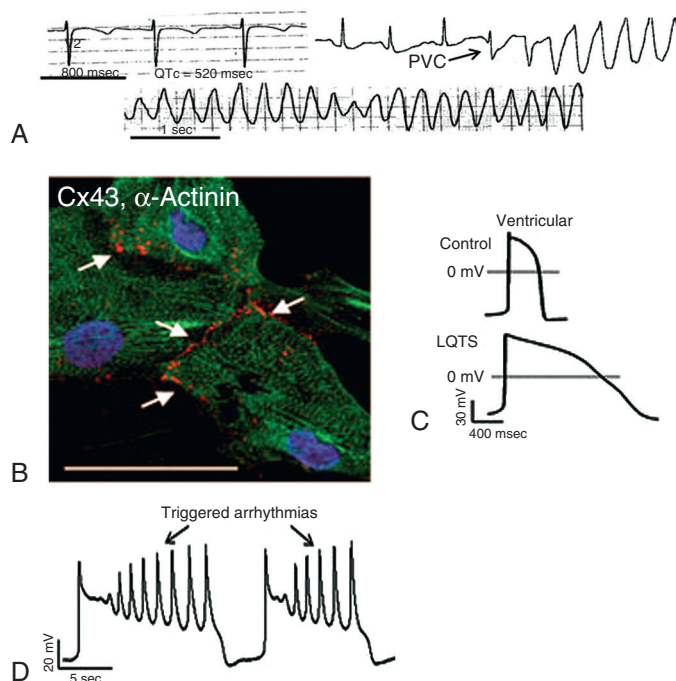

FIGURE e33-12 Recapitulation of LQTS via iPSC technology. **A**, Surface electrocardiogram from a 28-year-old woman with familial type-2 LQTS as a result of a loss-of-function mutation in the *KCNH2* gene, which encodes the pore-forming subunit of the HERG potassium channel (see Table 33-3). Tracings were recorded during sinus rhythm (upper left panel; the QT interval corrected for heart rate is 520 milliseconds) and during initiation (upper right panel) and sustenance of torsades de pointes. **B**, iPSC-derived cardiomyocytes in culture express structural markers of the cardiac lineage. Dermal fibroblasts were obtained from the LQTS patient above and were reprogrammed to generate LQTS patient-specific human iPSCs via transduction with a cocktail of transcription factors. These iPSCs were then induced to differentiate into cardiomyocytes. Immunocytochemistry revealed expression of sarcomeric alpha-actinin (green) and the gap junction protein connexin 43 (red; arrows) in LQTS cardiomyocytes. **C**, Transmembrane action potential recordings from LQTS ventricular cardiomyocytes revealed a markedly prolonged action potential duration relative to recordings obtained from healthy control patient iPSC-derived myocytes, consistent with a reduction in *KCNH2*-encoded I_{Kr} in the LQTS patient. **D**, Spontaneous development of repetitive EADs in LQTS cardiomyocytes. (From Itzhaki I, Maizels L, Huber I, et al: *Modelling the long QT syndrome with induced pluripotent stem cells*. *Nature* 471:225, 2011.)

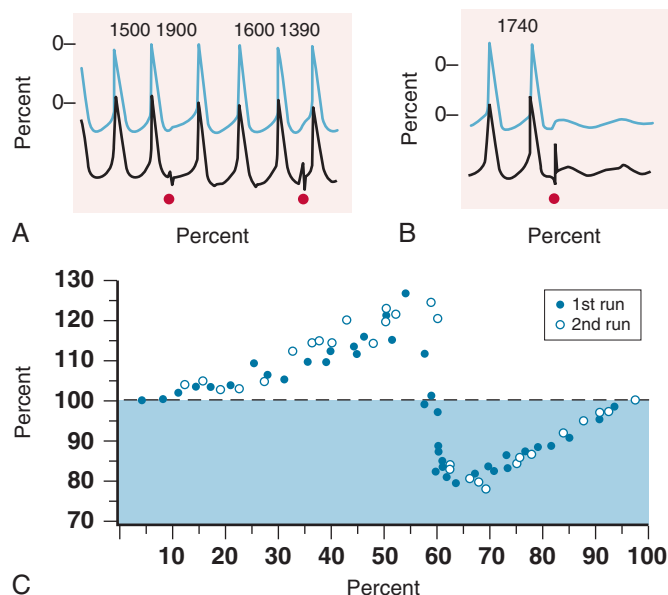

FIGURE e33-13 Modulation of pacemaker activity by subthreshold current pulses in diseased human ventricle. **A**, Two recording sites along the same trabecula in a spontaneously active preparation. Current pulses (indicated by the red dots) of 30 milliseconds in duration were injected through the lower microelectrode at various times. The interval between the spontaneous action potentials is given in milliseconds above each cycle. Injection of a subthreshold current pulse through the lower microelectrode relatively early in the spontaneous cycle (≈ 680 msec after initiation of the rapid portion of the preceding action potential upstroke) produced a subthreshold depolarization in the upper recording and delayed the next spontaneous discharge by 400 to 1900 milliseconds. This response curve would fall in the first half of the curve indicated in **C**. A current pulse of the same intensity and duration delivered later in the spontaneous cycle (950 msec after the preceding upstroke) accelerated the next discharge by 210 to 1390 milliseconds relative to the previous two action potentials. The response to this current injection falls in the second half of the graph depicted in **C**. **B**, A stimulus at a precise interval in the cardiac cycle (called the singular point; in this example, 930 msec after the preceding action potential upstroke) abolishes pacemaker activity. **C**, Phase-response curves from experimental data obtained in canine Purkinje fibers in a manner similar to that in the human experiment shown in **A** and **B**. Two different runs are shown. The ordinate in this graph is the percent age increase or decrease in spontaneous cycle length of the "parasystolic focus" (control cycle length equals 100%); the abscissa is the percentage of the "parasystolic focus" spontaneous cycle length during which stimulation was performed. The spontaneous cycle length was maximally prolonged (by 26%) or shortened (by 20%) by subthreshold depolarizations that entered the parasystolic focus after approximately 50% and 60% of the cycle had elapsed, respectively. Very similar curves can be plotted for patients with parasystole (e.g., see Figs. 9 and 10 in Zipes DP: Plenary lecture. *Cardiac electrophysiology: Promises and contributions*. *J Am Coll Cardiol* 13:1329, 1989). (**A**, **B**, From Gilmour RF Jr, Heger JJ, Prystowsky EN, et al: *Cellular electrophysiological abnormalities of diseased human ventricular myocardium*. *Am J Cardiol* 51:137, 1983; **C**, from Jalife J, Moe GK: *Effect of electronic potentials on pacemaker activity of canine Purkinje fibers and relation to parasystole*. *Circ Res* 39:801, 1976. FIGURE 33-22 A-E, Criteria for entrainment exemplified in a case of postinfarction ventricular tachycardia (VT). **A, left**, Two leads of the electrocardiogram of a VT and intracardiac recordings from a mapping catheter (Map) at a left ventricular site critical for VT continuation, as well as from the right ventricular apex (RV). Note the diastolic potential (red arrowhead) during VT. Recordings are similarly arranged in all subsequent panels. **A, right**, RV pacing in the setting of sinus rhythm. **B**, RV pacing at a cycle length (CL) slightly shorter than VT produces a QRS complex that is a blend between fully VT and fully paced ("fusion") complexes. All recordings are accelerated to the paced CL, and after pacing ceases, the same VT resumes. Each fused QRS complex is identical and the last beat is entrained, but surface fusion is absent. **C, D**, The same phenomena, but at shorter paced CLs. Note that the fused QRS complex appears to be more similar to pacing than it does to VT as the pacing CL shortens. **B-D**, Progressive degrees of fusion on the electrocardiogram. The Map recording of **B** through **D** also shows a progression of fusion, with both the morphology and timing of a portion of the electrogram changing with faster pacing. **E**, Finally, a still shorter paced CL results in a sudden change in both the Map electrogram (block in the small diastolic potential, red arrowhead) and the surface electrocardiogram, which is now fully paced. When pacing ceases, VT has been interrupted. **F**, Diagrammatic representation of the reentrant circuit during spontaneous atrial flutter (AFL) and transient entrainment of the AFL. **Left**, The reentrant circuit during spontaneous type I AFL. f = circulating wave front of the AFL. **Center**, Introduction of the first pacing impulse (X) during rapid pacing from a high atrial site during AFL. The large arrow indicates entry of the pacing impulse into the reentrant circuit, whereupon it is conducted orthodromically (Ortho) and antidromically (Anti). The antidromic wave front of the pacing impulse (X) collides with the previous beat, in this case the circulating wave front of the spontaneous AFL (f), which results in an atrial fusion beat and, in effect, terminates the AFL. However, the orthodromic wave front from the pacing impulse (X) continues the tachycardia and resets it to the pacing rate. **Right**, Introduction of the next pacing impulse (X + 1) during rapid pacing from the same high atrial site. The large arrow again indicates entry of the pacing impulse into the reentrant circuit, whereupon it is conducted orthodromically and antidromically. Once again, the antidromic wave front from the pacing impulse (X + 1) collides with the orthodromic wave front of the previous beat. In this case it is the orthodromic wave front of the previous paced beat (X), and an atrial fusion beat results. The orthodromic wave front from the pacing impulse (X + 1) continues the tachycardia and resets it to the pacing rate. In all three parts, arrows indicate the direction of spread of the impulses; the serpentine line indicates slow conduction through a presumed area of slow conduction (stippled region) in the reentrant circuit; and the red dots with tails indicate bipolar electrodes at the high atrial pacing site, the posteroinferior portion of the left atrium (PLA), and another atrial site. (**A-E**, From Zipes DP: A century of cardiac arrhythmia: In search of Jason's golden fleece. *J Am Coll Cardiol* 34:959, 1999; **F**, from Waldo AL: Atrial flutter. Entrainment characteristics. *J Cardiovasc Electrophysiol* 8:337, 1997.)

activation. Each pacing stimulus creates a wave front that travels in an anterograde direction (orthodromic) and resets the tachycardia to the pacing rate. A wave front propagating retrogradely in the opposite direction (antidromic) collides with the orthodromic wave front of the previous beat (Fig. 33-22B). These wave front interactions create electrocardiographic and electrophysiologic features that can be explained only by reentry. Therefore the criteria of entrainment can be used to prove the reentrant mechanism of a clinical tachycardia and form the basis for localizing the pathway traveled by the tachycardia wave front. Such localization is essential for ablation therapy.

Anatomic Reentry

Studies on reentry have used models with anatomically defined separate pathways in which it could be shown that they had an area of unidirectional block and recirculation of the impulse to its point of

origin. An example using AV nodal reentry is illustrated in Figure 33-23. Because the two pathways have different electrophysiologic properties (e.g., shorter refractory period and slower conduction in one pathway versus a longer refractory period and faster conduction of the other), the impulse is first blocked in one pathway with a longer refractory period (green area in Fig. 33-23) and then propagates slowly in the adjacent pathway whose refractory period is shorter (red area in Fig. 33-23A, right panel). If conduction in this alternative route is sufficiently depressed, the slowly propagating impulse excites tissue beyond the blocked pathway (see Fig. 33-23A, right panel, dashed yellow arrow) and returns in a reversed direction along the pathway initially blocked to reexcite tissue proximal to the site of block. A clinical arrhythmia caused by anatomic reentry is most likely to have a monomorphic contour (Video 33-3).¹¹

For reentry of this type to occur, the time for conduction within the depressed but unblocked area and for excitation of the distal segments must exceed the refractory period of the initially blocked pathway (Fig. 33-24A; also see Fig. 33-23 and Video 33-4, which shows electrical reentry in the infarct border zone) and the tissue proximal to the site of block. Stated another way, continuous reentry requires the anatomic length of the circuit traveled to equal or exceed the reentrant wavelength. The latter is equal to the mean conduction velocity of the impulse multiplied by the longest refractory period of the elements in the circuit. Both values can be different at different points along the reentry pathway, and thus the wavelength value is somewhat contrived.

Conditions for Reentry

The length of the pathway is fixed and determined by the anatomy. Conditions that depress conduction velocity or abbreviate the refractory period promote the development of reentry in this model, whereas prolonging refractoriness and speeding conduction velocity

**VIDEO 33-3**

Simulation of fast-slow reentry using an electroanatomical model. Responses to S1 and S2 stimuli are shown. S1-S2 interval is 96 ms. The preparation was stimulated at the His bundle as shown by the stimulating electrodes. There is a flash and click coincident with each stimulus. (From Li J, Greener ID, Inada S, et al: Computer three-dimensional reconstruction of the atrioventricular node. *Circ Res* 102:975, 2008.)

VIDEO 33-4

Simulation of electrical reentry in a three-dimensional model of the infarct border zone. The model was paced with a stimulus train at a basic cycle length of 300 ms (S_1) and the coupling interval (S_1S_2) was progressively reduced until block occurred. The subepicardial pacing site is marked by a red sphere in sequence 1 and 2. Activation sequences 1 and 2 were obtained during subepicardial pacing at a coupling interval of 157 ms. Propagation of beat 1 is blocked within the subepicardial border zone, but not across the junction of the border zone and the midwall or at the network boundary (green line), which connects the subepicardial and subendocardial border zones, although at reduced propagation speed. Paced beat 2 fails to propagate from the border zone to the midwall (unidirectional block) and stable re-entrant activation occurs. (From Rutherford SL, Trew ML, Sands GB, et al: High-Resolution 3-Dimensional Reconstruction of the Infarct Border Zone. *Circ Res* 2012 Jun 19.)

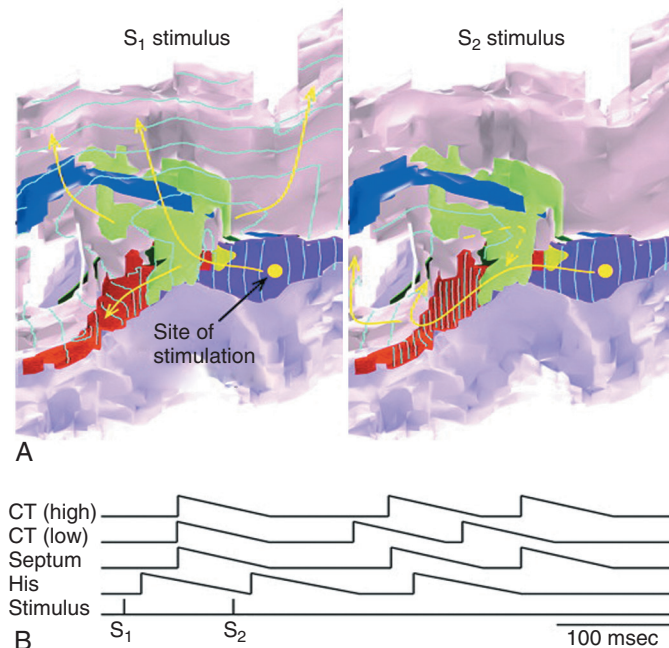

FIGURE 33-23 Simulation of reentry in a model of the AV node. **A**, Electrical stimuli are applied to the His bundle (yellow point) by using an S_1 - S_2 protocol (S_1 - S_2 interval, 96 milliseconds). The activation sequences (shown as isochrones at 5-millisecond intervals) in response to S_1 and S_2 stimuli are shown. Arrows highlight the conduction pathways. Two stimuli are delivered. The S_1 action potential exits into the atrial muscle via the transitional tissue (green area), the putative fast pathway. The premature S_2 action potential fails to exit via the transitional tissue because the S_1 - S_2 interval is shorter than the refractory period of the transitional tissue. Instead, the S_2 action potential exits into atrial muscle via the inferior nodal extension (INE, the putative slow pathway; red area) because the refractory period of the INE is shorter. The conduction velocity within the INE is low, as indicated by the isochrone crowding within the red area. The action potential then propagates anterogradely along the fast pathway (transitional tissue is no longer refractory) back into the His bundle. **B**, Simulated action potentials (at the high and low crista terminalis, interatrial septum, and His bundle) at different time points on the reentry circuit during S_1 - S_2 stimulation. The S_2 action potential retrogradely excites atrial tissue (the action potential at the low crista terminalis appears first) and then anterogradely the His bundle, thereby completing one reentry cycle. The reentry beat propagates along the INE and out into the atrial muscle once more but then fails to anterogradely reexcite the His bundle. Color coding of the various tissue types is the same as in Figure 33-7. (From Li J, Greener ID, Inada S, et al: Computer three-dimensional reconstruction of the atrioventricular node. *Circ Res* 102:975, 2008. By permission of the American Heart Association.)

can hinder it. For example, if conduction velocity (0.30 m/sec) and refractoriness (350 milliseconds) for ventricular muscle were normal, a pathway of 105 mm ($0.30 \text{ m/sec} \times 0.35 \text{ sec}$) would be necessary for reentry to occur. However, under certain conditions, conduction velocity in ventricular muscle and Purkinje fibers can be very slow (0.03 m/sec), and if refractoriness is not greatly prolonged (600 milliseconds), a pathway of only 18 mm ($0.03 \text{ m/sec} \times 0.60 \text{ sec}$) may be necessary. Such reentry frequently exhibits an excitable gap, that is, a time interval between the end of refractoriness from one cycle and the beginning of depolarization in the next, when tissue in the circuit is excitable. This condition results because the wavelength of the reentrant circuit is less than the length of the pathway. Electrical stimulation during this period can invade the reentrant circuit and reset its timing or terminate the tachycardia. Although “microanatomic” reentry (confinement of the reentrant circuit to a few adjacent myocytes) has been postulated to occur in fibrotic myocardium,⁹³ its occurrence in intact heart muscle has not been demonstrated directly. This difficulty results from the inability to unambiguously distinguish microreentry from triggered activity with currently available techniques.

Rapid pacing can entrain the tachycardia, that is, continuously reset it by entering the circuit and propagating around it in the same way as the reentrant impulse, which increases the tachycardia rate to the pacing rate without terminating the tachycardia (see

Fig. 33-22). In reentrant circuits with an excitable gap, conduction velocity determines the revolution time of the impulse around the circuit and therefore the rate of the tachycardia. Prolongation of refractoriness, unless it is long enough to eliminate the excitable gap and make the impulse propagate in relatively refractory tissue, does not influence the revolution time around the circuit or the rate of the tachycardia. Anatomic reentry occurs in patients with Wolff-Parkinson-White syndrome, in AV nodal reentry, in some atrial flutters, in some ventricular tachycardias, and in VF. For example, mapping studies in isolated ovine atria have demonstrated key roles of anatomic structures (e.g., fibrotic patches) in the maintenance of reentry during fibrillation.⁹⁴

Functional Reentry

Functional reentry lacks confining anatomic boundaries and can occur in contiguous fibers that exhibit functionally different electrophysiologic properties caused by local differences in transmembrane action potential (e.g., Purkinje-myocyte transition). Dispersion of excitability, refractoriness, or both, as well as anisotropic distributions of intercellular resistance, permit initiation and maintenance of reentry. Functional heterogeneity in the electrophysiologic properties of the myocardium has been shown to contribute to the generation and maintenance of tachycardia and fibrillation. These heterogeneities can be fixed, as in the case of spatial redistribution of gap junctions in the failing heart⁴⁹ or infarct border zone or in the case of spatial gradients in the magnitude of the background K^+ current I_{K1} (see Fig. 33-24B).⁹⁵ They can also change dynamically, as in an acutely ischemic myocardium⁹⁶ or in the presence of repolarization-prolonging agents.⁹⁷ A very important determinant of the dynamically induced component of heterogeneity has been identified as electrical restitution, or variation of the action potential duration and conduction velocity with the diastolic interval.⁹⁸ It has been proposed that the breakup of periodic waves is precipitated by oscillations in the action potential duration (so-called action potential duration alternans) of sufficiently large amplitude to cause conduction block along a spiral wave front (see Fig. 33-27).

Tachycardias Caused by Reentry

Reentry is probably the cause of many tachyarrhythmias, including various types of supraventricular and ventricular tachycardias, flutter, and fibrillation (see Chapter 37).

Atrial Flutter

Reentry is the most likely cause of the usual form of atrial flutter, with the reentrant circuit being confined to the right atrium in typical atrial flutter, where it usually travels counterclockwise in a caudocranial direction in the interatrial septum and in a craniocaudal direction in the right atrial free wall. An area of slow conduction is present in the posterolateral to posteromedial inferior area of the right atrium, along with a central area of block that can include an anatomic (inferior vena cava) and functional component. This area of slow conduction is rather constant and represents the site of successful ablation of atrial flutter. Ablation results are consistent with a macroreentry circuit.

Different reentrant circuits exist in patients with other types of atrial flutter, such as those that occur after surgery or ablation or are associated with an atrial septal defect (see Chapter 62).

Atrial Fibrillation

Spatiotemporal Organization and Focal Discharge

According to the multiple-wavelet hypothesis, AF is characterized by fragmentation of the wave front into multiple daughter wavelets (see Chapter 38). They wander randomly throughout the atrium and give rise to new wavelets that collide with each other and are mutually annihilated or that give rise to new wavelets in a perpetual activity.

The randomness of the irregular electrical activity during AF has been disputed on the basis of both statistical methods and

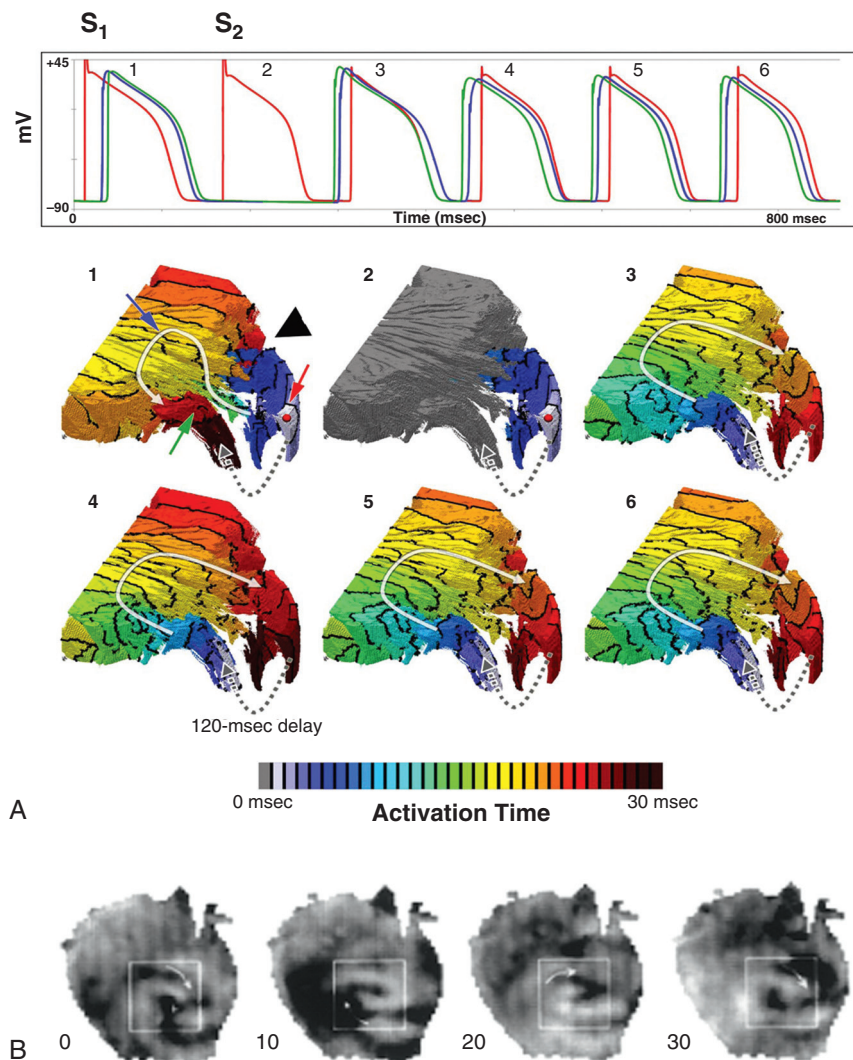

FIGURE 33-24 Models of reentry. **A**, Simulation of electrical reentry in the infarct border zone. Panels 1 through 6 show three-dimensional reconstructions of voltage activation in a high-resolution model of the infarct border zone during electrical stimulation at the subepicardial border zone (red sphere in panels 1 and 2) and during sustained electrical reentry (panels 3 through 6). The model was paced with a stimulus train at a basic cycle length of 300 milliseconds (S_1), and the coupling interval between S_1 and S_2 was progressively reduced until block occurred. The upper panel shows action potential traces at the subepicardial border zone (red), midwall (green), and subendocardial border zone (blue) sites indicated by arrows in panel 1. Numbers above the action potential trace correspond to the voltage activation sequences of beats 1 to 6. Beats 1 and 2 are paced with a coupling interval (S_1 - S_2) of 157 milliseconds. Propagation of beat 1 is blocked within the subepicardial border zone (arrowhead) but not at the junction of the border zone and the midwall (solid white line) or at the network boundary (dashed line), although conduction along these paths is slow. Beat 2 fails to propagate from the border zone to the midmyocardium (unidirectional block), and sustained reentrant activation occurs in beats 3 to 6. (For more on the activation time series, see Video 33-4.) **B**, Spiral wave model. Recording of spiral wave reentry during VF in a Langendorff-perfused guinea pig heart using a potentiometric fluorophore. Shown are the distributions of membrane potentials at four different times during one rotation on the left ventricular epicardial surface, with white and black being the most positive and most negative membrane potentials, respectively. Numbers are time in milliseconds. Arrows denote the direction of wave front propagation. (**A**, From Rutherford SL, Trew ML, Sands GB, et al: High-resolution 3-dimensional reconstruction of the infarct border zone. *Circ Res* 111:301, 2012; **B**, from Samie FH, Berenfeld O, Anumonwo J, et al: Background potassium current. A determinant of rotor dynamics in ventricular fibrillation. *Circ Res* 89:1216, 2001. By permission of the American Heart Association.)

experimental studies. A combination of high-resolution video imaging, recordings of the electrocardiogram, and spectral analysis was used to demonstrate that reentry in anatomically or functionally determined circuits forms the basis of spatiotemporal periodicity during acute AF. The cycle length of the source in the left atrium determines the dominant peak in the frequency spectra. The underlying periodicity may stem from a repetitive focal source of activity propagated from an individual pulmonary vein or left atrial site to the remainder of the atrium as fibrillating waves. If a single repetitive focal source of activity that undergoes fractionation underlies the maintenance of AF, ablation of this focal source should interrupt AF. Indeed, delivery of radio-frequency energy to discrete sites in the distal pulmonary veins in humans has been shown to eliminate or reduce recurrence of AF. In a large animal model of inducible AF associated with heart failure, it was recently demonstrated that AF dynamics is characterized by rapid repetitive activation (resulting from either microanatomic reentry or triggered activity) revolving around fibrotic obstacles in the posterior

left atrium or pulmonary vein ostia. Furthermore, fibrillatory activity was maintained by intramural reentry centered on fibrotic patches and appeared as endocardial breakthroughs at the posterior left atrium (endocardial breakthroughs are considered sudden and unexpected appearances of localized electrical activity not related to activation or slow conduction in the surrounding regions). In atria with heart failure, AF waves changed the origin and direction of propagation on a beat-to-beat basis, whereas in normal left atria, the breakthrough sites and direction of activation of AF wave fronts were highly recurrent from one AF wave to the next (Fig. e33-14 and Video 33-5). Interestingly, numeric simulations of AF dynamics best recapitulated the experimental observations in this study when cardiomyocytes were assumed to be electrotonically coupled to myofibroblasts, thus supporting a role of heterocellular electrical coupling in atrial arrhythmogenesis.⁹⁴

Several experimental models have been used to study the structural and basic electrophysiologic properties of pulmonary veins that

VIDEO 33-5

Phase movie of posterior left atrial activation during atrial fibrillation in an ovine heart with experimentally induced congestive heart failure, showing changing and peripherally located endocardial breakthroughs. The wavefront is depicted in blue-purple and the wavetail is shown in yellow. The phase movie was generated using the delay embedding method. (From Tanaka K, Zlochiver S, Vikstrom KL, et al: *Spatial distribution of fibrosis governs fibrillation wave dynamics in the posterior left atrium during heart failure*. *Circ Res* 101:839, 2007.)

are thought to play a role in initiation and maintenance of AF. Morphologic studies have demonstrated the presence of complex anatomic structures and phenotypically different cardiomyocytes in pulmonary veins.^{99,100} Electrophysiologic studies have shown that a combination of reentrant and nonreentrant mechanisms (automaticity and triggered activity) is the underlying arrhythmogenic mechanism for initiation of AF from the pulmonary veins.^{100,101} Abnormal intracellular calcium handling probably plays a pivotal role in the pulmonary vein electrical activity. Dual mapping of cardiomyocyte membrane potential and intracellular free calcium has demonstrated the appearance of spontaneous calcium release events resulting in focal discharge.⁹⁰ The role of dysfunction of calcium-handling proteins (e.g., $\text{Na}^+/\text{Ca}^{2+}$ exchanger, ryanodine receptor calcium release channels) in AF awaits further investigation.

Ion Channel Abnormalities in Atrial Fibrillation

Monogenic (Familial) Atrial Fibrillation. Although familial forms of AF are relatively rare, identification of mutations in AF kindreds has provided valuable insight into the molecular pathways underlying the arrhythmia.¹⁰² Most mutations linked to familial AF have been located in genes that encode sodium or potassium channel subunits. Functional analyses of these mutations have revealed either gain-of-function or loss-of-function effects. Mutations in genes encoding pore-forming α or auxiliary β subunits of the delayed rectifier potassium channel and the voltage-gated sodium channel (I_{Ks} and I_{Na} , respectively; see Table 33-3) have been reported in familial AF. The mechanisms by which these mutations cause AF are not clearly understood. Gain-of-function mutations in I_{Ks} give rise to increased repolarizing currents, which then shorten the action potential duration and atrial refractoriness, thereby facilitating fibrillatory activity. An augmented inward sodium current can induce triggered activity. Conversely, a reduced inward sodium current promotes reentry by abbreviating the action potential duration/refractoriness and thus the reentry wavelength. Other potassium channel mutations associated with AF have been localized to the *KCNJ2* and *KCNA5* genes, which encode the inward rectifier and ultrarapid delayed rectifier potassium current, respectively (see Table 33-3). Finally, mutations in the *GJA5* gene, which encodes the gap junction channel subunit connexin 40, have been linked to familial AF. Functionally, abnormal intercellular electrical coupling can result in conduction heterogeneity and facilitate reentry.

Genome-Wide Association Studies for Lone Atrial Fibrillation. Genome-wide association studies have identified variations in multiple genomic regions that are associated with lone AF.^{103,104} These regions encode ion channels (e.g., the calcium-activated potassium channel gene *KCNN3* and the HCN channel gene *HCN4*), transcription factors related to cardiopulmonary development (e.g., the homeodomain transcription factor *PRRX1*), and cell-signaling molecules (e.g., *CAV1*, a cellular membrane protein involved in signal transduction). The mechanistic links between these genetic variations and susceptibility to AF remain to be determined.

A number of experimental studies have probed the primary role of abnormalities in ion channel expression or properties in causing AF. Rapid pacing-induced AF in dogs causes a decrease in binding of FKBP-12.6 to the ryanodine receptor Ca^{2+} release channel (see Fig. e33-5), thereby resulting in diastolic SR Ca^{2+} leakage, which in turn, through activation of Ca^{2+} -sensitive currents, can initiate electrical instability and contribute to AF.¹⁰⁵ Mice with a genetic gain-of-function defect in the gene encoding the type 2 ryanodine receptor exhibit increased susceptibility to inducible AF. AF induction in this animal model may involve triggered activity arising from EADs, whereas maintenance of AF requires reentrant activity.⁸³ $\text{Cav}1.3$ Ca^{2+} channel-deficient mice exhibit increased susceptibility to inducible atrial flutter and AF.¹⁰⁶ Mice in which the gene encoding KCNE1, an auxiliary subunit of the pore-forming K^+ channel α subunit *KCNQ1*, has been knocked out display frequent spontaneous episodes of AF.¹⁰⁷

Electrical Remodeling of the Atria

Electrical remodeling of the atria appears to be a key determinant for maintenance of AF. Prolonged rapid atrial rates cause electrophysiologic alterations in the atria, including shortening and loss of the physiologic rate adaptation of refractoriness and a decrease in conduction velocity. Because abbreviation of the atrial refractory period is disproportionately larger than the reduction in conduction velocity, the wavelength of the reentrant wavelets shortens and thereby promotes reentrant activity.

The ionic basis of shortening of the refractory period and slowing of conduction may be a significant reduction in the density of the L-type Ca^{2+} and the fast Na^+ currents. The electrophysiologic changes are paralleled by similar decreases in messenger RNA levels of Ca^{2+} and Na^+ channel genes, which suggests alterations in gene expression as the underlying molecular mechanisms of atrial electrical remodeling. Changes in the density, spatial distribution, or both of various connexin types may also cause alterations in atrial impulse propagation. In addition, autonomic remodeling appears to play a key role in both triggering and maintaining AF. Long-term selective vagal denervation of the atria and sinoatrial and AV nodes prevents induction of AF. Heterogeneous sympathetic denervation of the atria favors the development of sustained AF.

Sinus Reentry

The sinoatrial node shares with the AV node electrophysiologic features such as the potential for dissociation of conduction, that is, an impulse can be conducted in some nodal fibers but not in others, thereby permitting reentry to occur (see Chapter 37). The reentrant circuit can be located entirely within the sinoatrial node or involve both the sinoatrial node and atrium. Supraventricular tachycardias caused by sinus node reentry are generally less symptomatic than other supraventricular tachycardias because of slower rates. Ablation of the sinoatrial node may occasionally be necessary for refractory tachycardia.

Atrial Reentry

Reentry within the atrium, unrelated to the sinoatrial node, can be a cause of supraventricular tachycardia in humans. Distinguishing atrial tachycardia caused by automaticity or afterdepolarizations from atrial tachycardia sustained by reentry over small areas (i.e., microanatomic reentry) is difficult.

Atrioventricular Nodal Reentry

Differences in the electrical properties of the various tissue types that contribute to the AV node are responsible for AV nodal reentrant tachycardia (AVNRT; see Figs. 33-7 and 33-23). Optical mapping of AV nodal transmembrane action potentials during echo beats reveals the reentrant pathways underlying the various types of AVNRT (Fig. 33-25; see also Fig. 33-7 for nomenclature of the AV nodal regions). The reentrant pathway of the slow-fast type starts counterclockwise with a block in the fast pathway (the transitional zone; see the light green area in Fig. 33-7), delay in conduction across the slow pathway (the inferior nodal extension; see the red area in Fig. 33-7) to the compact AV node (triangular-shaped, colored area to the left of black dot 4 in Fig. 33-7), exit from the AV node to the fast pathway, and rapid return to the slow pathway through atrial tissue located at the base of the triangle of Koch. The reentrant circuit of the fast-slow type is clockwise. In the slow-slow type, anterograde conduction is over the intermediate pathway and retrograde conduction is over the slow pathway. Because slow-pathway conduction is involved in each type of AVNRT, ablation of the slow pathway is effective for all types of AVNRT. These results also demonstrate that atrial tissue surrounding the triangle of Koch is clearly involved in all three types of AV nodal reentry in these examples.

Preexcitation Syndrome

In most patients who have reciprocating tachycardias associated with Wolff-Parkinson-White syndrome, the accessory pathway conducts more rapidly than the normal AV node but takes a longer time to recover excitability; that is, the anterograde refractory period of the accessory pathway exceeds that of the AV node at long cycles. Consequently, a premature atrial complex that occurs sufficiently early is blocked anterogradely in the accessory pathway and continues to the ventricle over the normal AV node and His bundle. After the ventricles have been excited, the impulse is able to enter the accessory pathway retrogradely and return to the atrium. A continuous conduction loop of this type establishes the circuit for the tachycardia. The usual (orthodromic) activation wave during such a reciprocating tachycardia in a patient with an accessory pathway occurs anterogradely over the normal AV node–His-Purkinje system

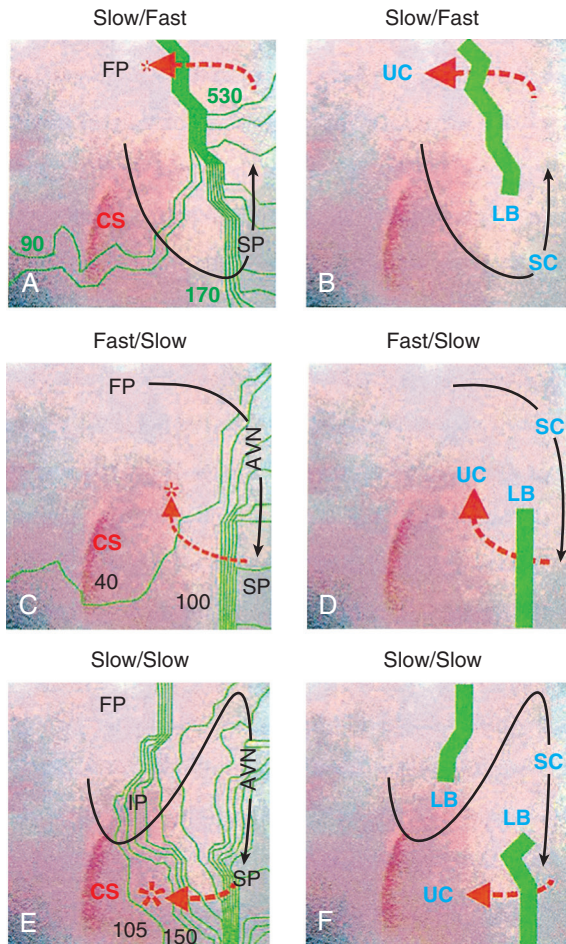

FIGURE 33-25 Reentrant circuits of different types of AVNRT. Pictures of the optical activation maps of A_2 obtained from three different experiments at A_2 coupling intervals of 190, 220, and 190 milliseconds, respectively, were merged with the pictures of the mapping area to show the initiation of echo beats in **A** (Slow/Fast), **C** (Fast/Slow), and **E** (Slow/Slow). The numbers on the maps indicate the activation times in reference to the A_2 stimulus. The black arrow indicates anterograde conduction, and the asterisk and the dashed red arrow represent the site of earliest retrograde atrial activation. The corresponding locations of the lines of block (LB, green), slow anterograde conduction (SC, black arrow), and unidirectional conduction (UC, red) are shown in **B**, **D**, and **F**, respectively. CS = coronary sinus; FP = fast pathway; IP = intermediate pathway; SP = slow pathway. (From Wu J, Zipes DP: Mechanisms underlying atrioventricular nodal conduction and the reentrant circuit of atrioventricular nodal reentrant tachycardia using optical mapping. *J Cardiovasc Electrophysiol* 13:831, 2002.)

and retrogradely over the accessory pathway, which results in a normal QRS complex (Fig. 33-26).

Because the circuit requires both atria and ventricles, the term *supraventricular tachycardia* is not precisely correct, and the tachycardia is more accurately termed *atrioventricular reciprocating tachycardia* (AVRT). The reentrant loop can be interrupted by ablation of the normal AV node–His bundle pathway or the accessory pathway. On occasion, the activation wave travels in a reverse (antidromic) direction to the ventricles over the accessory pathway and to the atria retrogradely up the AV node. Two accessory pathways can form the circuit in some patients with antidromic AVRT. In some patients the accessory pathway may be capable of only retrograde conduction (“concealed”), but the circuit and mechanism of AVRT remain the same. Less commonly, the accessory pathway can conduct only anterogradely. The pathway can be localized by analysis of the scalar electrocardiogram. Patients can have AF as well as AVRT. Developmental studies in mice have demonstrated that myocardium-specific inactivation of T-box 2, a transcription factor essential for AV canal patterning, leads to the formation of fast-conducting accessory path-

ways, malformation of the annulus fibrosus, and ventricular preexcitation in mice (Fig. e33-15).¹⁰⁸

Unusual accessory pathways with AV node–like electrophysiologic properties, that is, nodofascicular or nodoventricular fibers, can constitute the circuit for reciprocating tachycardias in patients who have some form of Wolff-Parkinson-White syndrome. Tachycardia in patients with nodoventricular fibers can be caused by reentry, with these fibers being used as the anterograde pathway and the His-Purkinje fibers and a portion of the AV node being used retrogradely. In the putative Lown-Ganong-Levine syndrome (short PR interval and normal QRS complex), conduction over a James fiber that connects the atrium to the distal portion of the AV node and His bundle has been proposed, although little functional evidence exists to support the presence of this entity.

Ventricular Tachycardia Caused by Reentry

Reentry in the ventricle, both anatomic and functional, as a cause of sustained ventricular tachycardia has been supported by many animal and clinical studies (see Fig. 33-24 and Chapter 37). Reentry in ventricular muscle, with or without contributions from specialized tissue, is responsible for many or most ventricular tachycardias in patients with ischemic heart disease. The area of microreentry appears to be small, and less commonly a macroreentry is found around the infarct scar. Surviving myocardial tissue separated by connective tissue provides serpentine routes of activation traversing infarcted areas that can establish reentry pathways. Bundle branch reentry can cause sustained ventricular tachycardia, particularly in patients with dilated cardiomyopathy.

Both figure-of-8 and single-circle reentrant loops have been described as circulating around an area of functional block in a manner consistent with the leading circle hypothesis or as conducting slowly across an apparent area of block created by anisotropy.¹⁰⁹ When intramural myocardium survives, it can form part of the reentrant loop. Structural discontinuities that separate muscle bundles—as a result of naturally occurring myocardial fiber orientation and anisotropic conduction, for example, as well as collagen matrices formed from the fibrosis after a myocardial infarction—establish the basis for slowed conduction, fragmented electrograms, and continuous electrical activity, which can lead to reentry. After the infarction, the surviving epicardial border zone undergoes substantial electrical remodeling,¹¹⁰ including reduced conduction velocity and increased anisotropy associated with the occurrence of reentrant circuits and ventricular tachycardia.⁴³ Slowing of conduction arises from alterations in the spatial distribution and electrophysiologic properties of connexin 43 gap junctions,⁴³ as well as from reduced voltage-gated sodium current. Whether myocyte depolarization secondary to electrotonic coupling to adjacent myofibroblasts (which typically have a much more depolarized potential) plays a role in electrical remodeling in postinfarction border zone myocardium remains to be seen.⁶⁶ During acute ischemia, various factors, including elevated $[K]_o$ and reduced pH, combine to create depressed action potentials in ischemic cells that retard conduction and can lead to reentry. Indeed, optical mapping studies in arterially perfused canine wedge preparations during global no-flow ischemia have demonstrated initiation of reentry during initial ischemia and subsequent reperfusion caused by the unidirectional block of conduction resulting from the spatiotemporal dispersion in tissue responses to stimulation.⁹⁷ The rapidly changing combination of transmural dispersion in response to endocardial pacing stimuli and the velocity of conduction creates a dynamic substrate in which reentry can be initiated and sustained. The results of this study are compatible with previous observations that fibrillation during reperfusion can be caused by intramural reentry. Interestingly, transmural reentry under these experimental conditions could be triggered by epicardial but not by endocardial stimulation at a time when there was an epicardial conduction delay or block with preserved endocardial conduction because of the increased susceptibility of the epicardium to the effects of ischemia. Clinically, this might facilitate induction of tachycardia by a PVC arising in the epicardium but not in the endocardium.

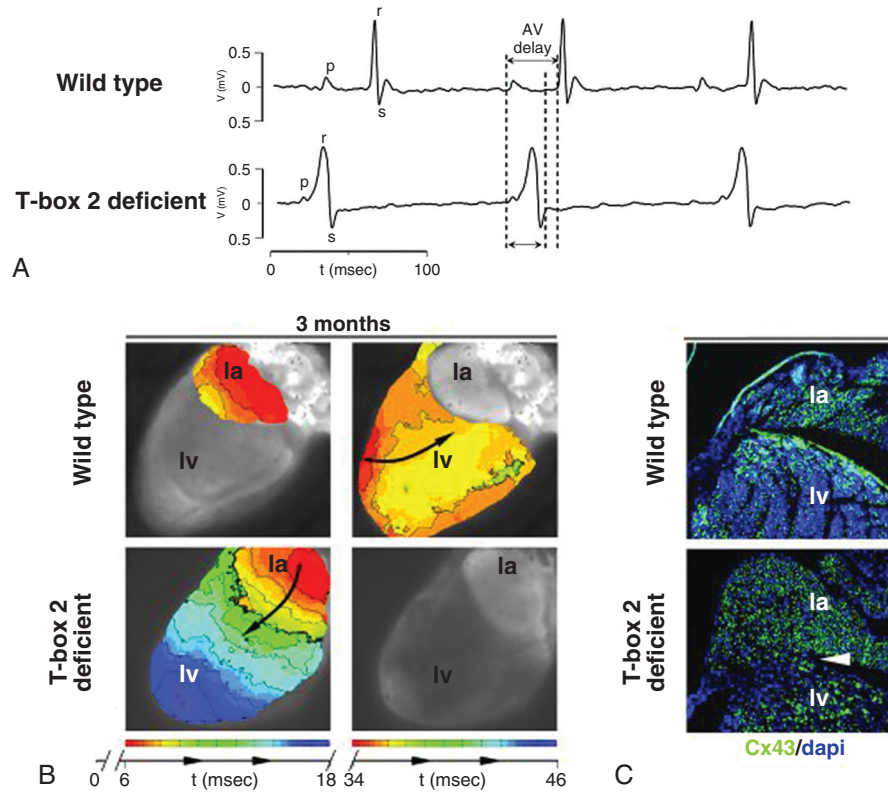

FIGURE e33-15 Accessory pathway formation in a mouse model of ventricular preexcitation. **A**, Surface electrocardiograms from an adult wild-type mouse and mouse with cardiomyocyte-specific inactivation of T-box 2, a transcription factor essential for AV canal patterning during development. Myocardial T-box 2 deficiency resulted in a severely shortened PR interval with a broadened QRS complex and initial slurring consistent with ventricular preexcitation. The total activation time of the atria and ventricles with preexcitation is less than the normal AV delay, thus indicating that the AV node is not used to activate (part of) the ventricle. Hence, these QRS complexes are not a representation of fusion of normal activation and preexcitation via the accessory pathway. **B**, Isochrone activation maps in an adult wild-type and T-box 2-deficient heart. In the wild-type heart, after an AV delay of 34 milliseconds, the ventricle is activated from the apex to the base. In the T-box 2-deficient heart, the ventricle is activated from the base to the apex after an AV delay of 9 milliseconds. **C**, Immunohistochemical analyses revealed connexin 43 expression (Cx43; green) in accessory myocardial connections between the left atrium (la) and the left ventricular (lv) base in the T-box 2-deficient heart (blue: nuclei). (From Aanhaanen WT, Boukens BJ, Sizarov A, et al: Defective Tbx2-dependent patterning of the atrioventricular canal myocardium causes accessory pathway formation in mice. *J Clin Invest* 121:534, 2011.)

FIGURE 33-26 A, Wolff-Parkinson-White syndrome. Following high right atrial pacing at a cycle length of 500 milliseconds (S_1 - S_1), premature stimulation at a coupling interval of 300 milliseconds (S_1 - S_2) produces physiologic delay in AV nodal conduction, which results in an increase in the A-H interval from 100 to 140 milliseconds but no delay in the AV interval. Consequently, activation of the His bundle follows activation of the QRS complex (second interrupted line), and the QRS complex becomes more anomalous in appearance because of increased ventricular activation over the accessory pathway. **B**, Induction of reciprocating AV tachycardia. Premature stimulation at a coupling interval of 230 milliseconds prolongs the A-H interval to 230 milliseconds and results in anterograde block in the accessory pathway and normalization of the QRS complex (a slight functional aberrancy in the nature of incomplete right bundle branch block occurs). Note that H_2 precedes onset of the QRS complex (interrupted line). Following V_2 , the atria are excited retrogradely (A') beginning in the distal coronary sinus, followed by atrial activation in leads recording from the proximal coronary sinus, His bundle, and high right atrium. A supraventricular tachycardia is initiated at a cycle length of 330 milliseconds. I, II, III, and V_1 indicate scalar electrocardiographic leads. A = H-V, atrial, His bundle, and ventricular activation during the drive train; A_2 = H_2 , V_2 , atrial, His bundle, and ventricular activation during the premature stimulus; DCS = distal coronary sinus electrogram; HBE = His bundle electrogram; HRA = high right atrium; PCS = proximal coronary sinus electrogram; RV = right ventricular electrogram. Time lines are in 50- and 10-millisecond intervals. S_1 = stimulus of the drive train; S_2 = premature stimulus. (From Zipes DP, Mahomed Y, King RD, et al: Wolff-Parkinson-White syndrome: Cryosurgical treatment. *Indiana Med* 89:432, 1986.)

Brugada Syndrome

Phase 2 reentry has been implicated in the genesis of ventricular tachycardia-fibrillation associated with the inheritable Brugada syndrome,¹¹¹ which is characterized by ST-segment elevation (unrelated to ischemia, electrolyte abnormalities, or structural heart disease) in

the right precordial (V_1 to V_3) leads of the electrocardiogram, often but not always accompanied by an apparent right bundle branch block. The hereditary nature of the syndrome is well established. Brugada syndrome has been linked to loss-of-function mutations in *SCN5A*, which encodes the pore-forming cardiac sodium channel

alpha subunit Nav1.5, and mutations in *SCN1B*, which encodes the function-modifying sodium channel beta₁ subunit (see Chapter 32).^{112,113} Although Na⁺ channel mutations are most common, mutations in the alpha and beta subunits of the Ca²⁺ channel gene have been found in some patients with Brugada syndrome, as have mutations in the glycerol-3-phosphate dehydrogenase 1-like gene (*GPD1L*) on chromosome 3p22-25 (BS2), which reduce the Na⁺ current I_{Na}. Brugada syndrome–associated gene defects cause a reduction or loss of sodium or calcium current in combination with altered functional properties of voltage-gated sodium channels. Alterations in the sodium channel current cause heterogeneous loss of the action potential dome during the plateau phase (phase 2) in the right ventricular epicardium, which leads to a marked dispersion of repolarization and refractoriness and the potential for phase 2 reentry.¹¹⁴ Ablation of right ventricular epicardium eliminated ventricular arrhythmias in an animal model of pharmacologically induced Brugada syndrome.¹¹¹

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is an inherited arrhythmogenic disease characterized by stress-induced, adrenergically mediated polymorphic ventricular tachycardia occurring in structurally normal hearts. Heterozygous missense mutations in the gene encoding the RyR2 have been reported in most patients with CPVT, although mutations in the calsequestrin gene can also cause CPVT.¹¹⁵ A common mechanism underlying RyR2-associated CPVT is increased leakage of Ca²⁺ from the SR during diastole leading to intracellular Ca²⁺ waves and triggered activity.^{76,116} Carvedilol, a beta blocker used for prevention of ventricular tachyarrhythmias in heart failure, and flecainide, a blocker of voltage-gated sodium channels, have recently been shown to suppress CPVT via direct inhibition of cardiac ryanodine receptor–mediated Ca²⁺ release, thus indicating that these agents possess hitherto unknown pharmacologic properties that can be exploited for the treatment of Ca²⁺-dependent arrhythmias in the clinical setting.^{117,118}

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is also an inherited disease characterized by sustained monomorphic ventricular tachycardia and sudden death. Previous studies have linked ARVC with mutations in proteins of the cardiac desmosome, a component of the intercalated disc essential for mechanical coupling between cardiomyocytes. Mutations in multiple genes, including desmoplakin, desmoglein 2, desmocollin 2, plakophilin 2, plakoglobin (JUP, also called gamma-catenin), ryanodine receptor 2, laminin receptor 1, and transforming growth factor-beta 3, have been identified in patients with ARVC. Approximately 70% of the mutations linked to inherited ARVC are in the gene encoding plakophilin 2 (*PKP2*), which interacts with other cytoskeletal proteins to stabilize the desmosome. In vitro studies have demonstrated that loss of *PKP2* expression reduces the voltage-gated sodium current and connexin 43 expression at the intercalated disc and thus results in slowed action potential propagation. Cardiomyocyte-specific inactivation of JUP in mice has recently been shown to recapitulate many aspects of the human ARVC phenotype, including ventricular dilation, cardiac fibrosis, ventricular dysfunction, and tachyarrhythmias.¹¹⁹

Ventricular Fibrillation: Initiation and Maintenance

Previous experimental and simulation investigations have suggested that VF is maintained solely by reentry (see Chapter 37). This reentry was thought to be unstable and to be maintained by wandering wavelets of activation following constantly changing paths of activation and exhibiting frequent conduction block caused by nonuniform dispersion of refractoriness. More recent investigations have suggested other mechanisms of maintenance of VF and have introduced the concepts of restitution kinetics, wave front, wave break, focal discharge, and rotor as replacement for the classic reentry theory.¹²⁰ (For a demonstration of wave front dynamics during fibrillation, see Video 33-6.)

The hallmark of cardiac fibrillation is ongoing wave break (or wave splitting).¹²¹ Wave break is caused by a conduction block occurring at a specific site along the wave front while the remaining portions of

the front continue to propagate. This localized block, wave break, causes splitting of the mother wave front into two daughter wavelets. Two hypotheses exist in regard to the genesis of wave breaks during fibrillation. The mother rotor hypothesis states that VF is maintained by a single, stationary, intramural stable reentrant circuit (i.e., the mother rotor) in a dominant domain, which has the shortest refractory period from which activations propagate into the more slowly activating domains with longer refractory periods. Wave breaks result from Wenckebach-like conduction as high-frequency impulses emanating from the dominant domain are unable to sustain 1:1 conduction through heterogeneous tissue. In this case the fastest activating (i.e., dominating) rotor rather than ongoing wave break is the engine driving cardiac fibrillation, and wave break occurs only secondarily.^{120,122} Evidence supporting this concept is that frequency analyses have shown (1) single, stable (both in space and time), dominant frequencies in the power spectra of membrane voltage signals obtained from various regions of the heart; (2) correlation of dominant frequencies and the frequency of reentry; (3) relative infrequency of reentry on the surface of the heart during fibrillation, with an intramural location of the mother rotor being favored, such as the Purkinje network; and (4) Wenckebach-like conduction at the borders between different dominant frequency domains. These borders can result from preexisting structural or functional heterogeneities. For example, high-resolution electrical mapping has suggested that fast activation during VF is driven by Purkinje fibers. Spatial heterogeneity in the magnitude of ionic currents has been implicated in the generation of spatial gradients in activation rates and in maintaining rotor stability in the fastest activating regions. For example, the magnitude of the inward rectifying K⁺ current I_{K1} (see Table 33-3) was larger in the rapidly activating left ventricular myocytes than in the slower activating right ventricular myocytes.⁷⁸ Furthermore, regions with larger I_{K1} had faster activation rates and more stable rotors than did regions with smaller I_{K1}.⁷⁷

In contrast to the stable mother rotor theory, other experimental evidence has supported the idea that dynamic wave break plays a fundamental role in the initiation and maintenance of short-duration VF (wandering wavelet hypothesis).^{120,121,123,124} According to this hypothesis, VF is maintained by wandering wavelets with constantly changing, evanescent, reentrant circuits. Experimental evidence favoring the multiple-wavelet hypothesis includes (1) an inability to detect a single dominant frequency in the power spectra of mapping data from fibrillating hearts; (2) spatiotemporal instability of frequency domain distributions during VF, with the exception of anatomic borders, such as the Purkinje-myocyte transition; (3) failure to demonstrate stable intramural reentry at higher frequencies than at the surface; and (4) boundaries dynamically generated by wavelet behavior rather than by anatomic conduction block. To reproduce the dynamic spatiotemporal instability of dominant frequency domains, a combination of dynamically changing and fixed tissue heterogeneity is required.⁹⁹ The most important determinant of the dynamically induced component of heterogeneity has been identified as electrical restitution, or variation of the action potential duration and conduction velocity with the diastolic interval. For example, it has been proposed that the breakup of periodic waves is precipitated by oscillations in the action potential duration (so-called action potential duration alternans [APD alternans]) that are sufficiently large to cause a conduction block along the spiral wave front. Simulations (Fig. 33-27) have shown that a reentrant rotor becomes unstable and breaks down into multiple rotors when the slope of the restitution curve for the action potential duration versus the diastolic interval is greater than 1. Pharmacologic blockade of the L-type calcium current can terminate VF by reducing the action potential duration restitution slope (see Fig. 33-27).¹²⁵ If it is occurring in a spatially discordant pattern, alternans is considered a key arrhythmogenic factor predisposing the heart to reentry and fibrillation.¹²⁶ At the cellular level, the origin of APD alternans appears to be determined primarily by alternations in cardiomyocyte calcium transient amplitude or duration (calcium alternans).

During spatially discordant alternans, the action potential duration alternates out of phase in different regions of the heart, thereby increasing dispersion of refractoriness so that ectopic beats have a high probability of inducing reentry. This mechanism is illustrated in Figure 33-28; some regions of the heart alternate in a long-short-long pattern, whereas other regions at the same time alternate in a short-long-short pattern. These out-of-phase regions are separated by a nodal line in which no alternans is present, but spatial gradients in the action potential duration are steepest along this line. Thus spatially discordant alternans creates gradients in tissue refractoriness,

Recording of spiral wave reentry during ventricular fibrillation in a Langendorff-perfused guinea pig heart using a potentiometric dye. Shown are the spatiotemporal dynamics of membrane potential changes on the left ventricular surface, with white and black being the most positive and most negative membrane potentials, respectively. (From Samie FH, Berenfeld O, Anumonwo J, et al: Background potassium current. A determinant of rotor dynamics in ventricular fibrillation. *Circ Res* 89:1216, 2001.)

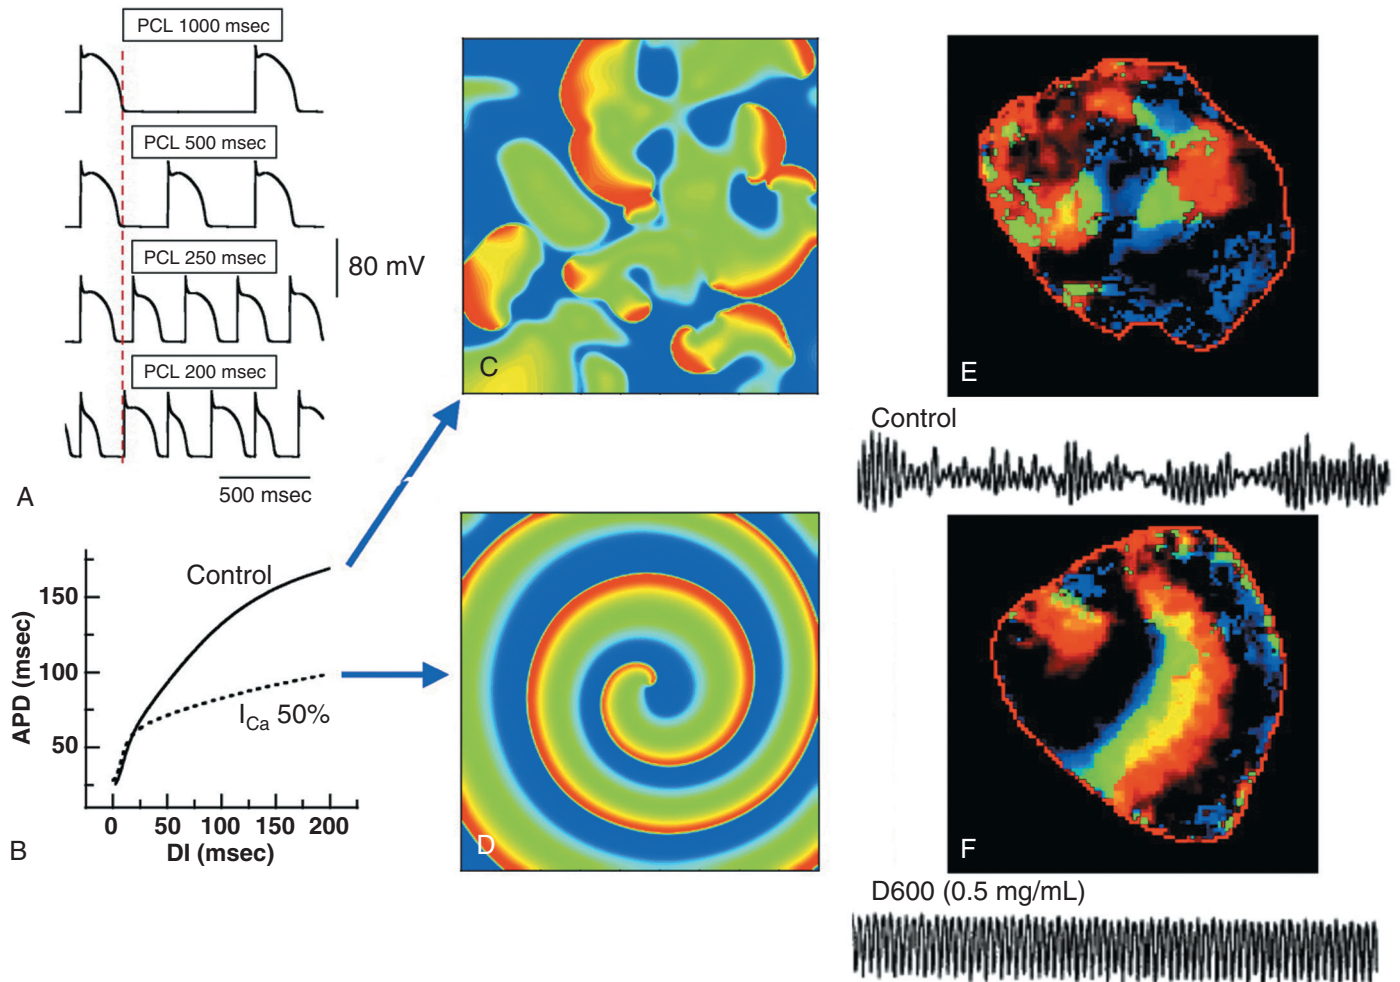

FIGURE 33-27 Action potential duration (APD) restitution slope and rotor stability. **A**, APD shortening and APD alternans as the pacing cycle length (PCL) decreases (computer simulations). **B**, APD restitution curves with a slope greater than 1 (solid line) or less than 1 (dashed line, obtained with 50% block of the calcium current). **C**, **D**, Spiral wave behavior several seconds after initiating a rotor in homogeneous two-dimensional tissue. All myocytes are assumed to be identical, with either a steep (**C**) or shallow (**D**) APD restitution slope. **E**, **F**, Conversion of multiple-wavelet VF to mother rotor VF. Optically measured surface voltage maps were obtained from an intact Langendorff-perfused rabbit heart before (**E**) and after (**F**) partially blocking the L-type calcium current to flatten the APD restitution slope to less than 1. In **E**, multiple wave fronts move in a complex VF pattern. In **F**, VF has converted to ventricular tachycardia, manifested as a stable rotor. Black tracings below the color panels in **E** and **F** are corresponding electrograms. DI = diastolic interval. (From Weiss JN, Qu Z, Chen PS, et al: The dynamics of cardiac fibrillation. *Circulation* 112:1232, 2005. By permission of the American Heart Association.)

which in turn favor the development of reentry by a premature beat (Fig. 33-28B). At the cellular level, the steepness of the action potential duration restitution curve and intracellular calcium level ($[Ca^{2+}]_i$) dynamics cause the action potential duration and $[Ca^{2+}]_i$ transient to alternate. Given the bidirectional coupling between changes in $[Ca^{2+}]_i$ and membrane potential—for example, the membrane potential determines the activity of L-type Cav channels, and conversely, the $[Ca^{2+}]_i$ transient amplitude strongly modulates the action potential duration through its effects on Ca^{2+} -sensitive currents (e.g., $I_{Na/Ca}$) during the action potential plateau—an alternation in $[Ca^{2+}]_i$ transient amplitude can cause a secondary alternation in the action potential duration. Indeed, experimental evidence has strongly suggested that the onset of APD alternans is primarily attributable to instabilities in $[Ca^{2+}]_i$ cycling dynamics, thus defining a causal role of intracellular Ca^{2+} -handling abnormalities in initiating electrical instability. At the tissue level, alternans combines with instabilities in conduction velocity to cause alternans to become spatially discordant. T wave alternans is the electrocardiographic manifestation of action potential duration $[Ca^{2+}]_i$ alternans and thus is a clinical predictor of future arrhythmic events.

In addition to a role of Purkinje fibers in the initiation of VF, other studies have suggested involvement of Purkinje fibers in the maintenance of VF, either as part of a reentrant circuit or as a source of focal activation. Their role appears to be more important during later (>1 minute) than during earlier stages of VF.¹⁰⁰

Ventricular Tachycardias Caused by Nonreentrant Mechanisms

In some cases of ventricular tachycardia related to coronary artery disease, especially in patients without coronary artery disease, nonreentrant mechanisms are important causes of ventricular tachycardias. However, in many patients the mechanism of the ventricular tachycardia remains unknown.

Triggered Activity

A group of probably nonreentrant ventricular tachycardias occurring in the absence of structural heart disease can be initiated and terminated by programmed stimulation. They are catecholamine dependent and can be terminated by the Valsalva maneuver, adenosine, and verapamil. These ventricular tachycardias are generally but not exclusively located in the right ventricular outflow tract and may be caused by triggered activity, possibly DADs that are cAMP dependent.⁵⁹ EADs have been recorded in this tachycardia as well. Left ventricular fascicular tachycardias can be suppressed by verapamil but not generally by adenosine, and some may be caused by triggered activity and others by reentry. EADs and triggered activity may be responsible for torsades de pointes.

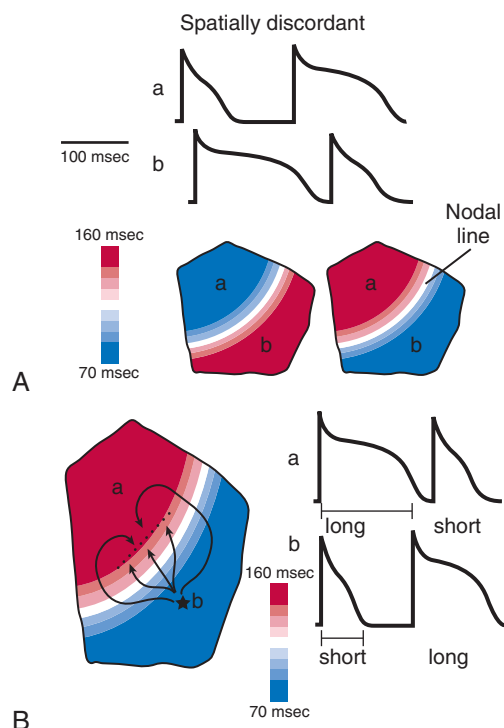

FIGURE 33-28 Initiation of reentry by a premature beat during spatially discordant alternans. **A, upper panel,** At rapid rates, action potentials at site a alternate short-long, whereas at the same time, action potentials at site b alternate long-short, thereby creating a steep gradient of action potential duration (APD) distribution with a nodal line that has no APD alternation separating the out-of-phase regions a and b (**lower panel**). **B,** A premature beat (asterisk) occurring in region b blocks (dotted line) as it propagates across the nodal line into the region with a long APD (a). The premature beat propagates laterally along the nodal line while waiting for the long APD region to repolarize and then reenters the blocked region to initiate figure-of-8 reentry. (From Weiss JN, Karma A, Shiferaw Y, et al: *From pulsus to pulseless: The saga of cardiac alternans*. *Circ Res* 98:1244, 2006. By permission of the American Heart Association.)

Automaticity

Automatic discharge can be responsible for some ventricular tachycardias and does not appear to be suppressed by adenosine. Unless invasive studies are undertaken, mechanisms of ventricular tachycardia can only be conjectured.

Molecular Composition of Ion Channels

Voltage-Gated Na⁺ Channels

Voltage-gated Na⁺ (Nav) channel pore-forming (alpha) subunits have four homologous domains (I to IV), each of which contains six transmembrane-spanning regions, and these four domains come together to form the Na⁺ permeable pore (see Fig. 33-11).¹ Among the multiple Nav alpha subunits, Nav1.5 (which is encoded by the *SCN5A* gene) is the prominent Nav alpha subunit expressed in mammalian myocardium. The name of the voltage-gated sodium channel consists of the chemical symbol of the principal permeating ion (Na) and v, which indicates its principal physiologic regulator (voltage). The number following v indicates the gene subfamily (Nav1), and the number following the decimal point identifies the specific channel isoform (e.g., Nav1.1). An identical nomenclature applies to voltage-gated calcium and potassium channels. Mutations in the sequence linking domains III and IV in *SCN5A*, which are associated with LQT3 syndrome, disrupt Nav channel inactivation and thereby give rise to a sustained inward Na⁺ current during the plateau phase of the action potential and to prolongation of the action potential. Cases of sudden infant death syndrome in black Americans have been linked to a polymorphism in the *SCN5A* gene, which encodes a variant cardiac sodium channel with diminished channel inactivation in the presence of lowered intracellular pH.² Mutations in *SCN5A* are also linked to Brugada syndrome. Brugada syndrome mutations result in reduced Nav current amplitude, which leads to slowing of phase 0 action potential upstroke, reduced action potential amplitude, and altered phase 1 repolarization.

Nav1.5 pore-forming alpha subunits coassemble with one to two auxiliary Nav beta subunits to form functional cell surface Nav channels in cardiomyocytes. Nav beta subunits appear to play an important role in anchoring ion channel proteins to the outer cell membrane.

Voltage-Gated Ca²⁺ Channels

Like Nav channels, cardiac voltage-gated Ca²⁺ (Cav) channels are assemblies of a pore-forming alpha subunit and auxiliary Cav beta or Cav alpha₂-delta subunits (see Fig. 33-11). Among the various alpha subunits, Cav1.2, encoded by the *CACNA1C* gene, is the prominent Cav alpha subunit expressed in mammalian myocardium. Cav1.2 channels exhibit many of the time- and voltage-dependent properties and pharmacologic sensitivities of cardiac L-type Ca²⁺ currents (see Table 33-3). Accessory subunits modulate the functional properties of Cav channels.

Cav3.1/alpha₁G alpha subunits form a Ca²⁺-selective channel with time- and voltage-dependent characteristics and pharmacologic sensitivities that resemble those of the low-voltage activated T-type Ca²⁺ channel. Disruption of the gene encoding Cav3.1/alpha₁G alpha subunits (*CACNA1G*) in mice has been demonstrated to slow the sinus node rate and AV conduction, consistent with its role in sinoatrial and AV node function.³

Voltage-Gated K⁺ Channels

Voltage-gated K⁺ channels (Kv) are composed of four separate pore-forming (alpha) subunits, each containing six regions (S₁ through S₆) of hydrophobic amino acids that are thought to form membrane-spanning domains (see Fig. 33-11).¹ Kv alpha subunits expressed in the human heart include members of the Kv1, Kv4, hERG, and KvLQT subfamilies. In addition, Kv channel alpha subunit proteins interact with Kv channel accessory subunits, including minK, KChIP2, and MiRP1 (see Table 33-3), to form functional cell surface channels with distinct time- and voltage-dependent properties. Coassembly of the Kv4.3 alpha subunits and the accessory subunit KChIP2 gives rise to the cardiac transient outward Kv channel I_{to}. ERG1 alpha subunits, together with MiRP1 accessory subunits, contribute to the generation of functional cardiac I_{Kr} channels. Mutations in the gene encoding ERG1 (*KCNH2*) have been shown to underlie congenital LQT2

syndrome. These LQT2 syndrome mutations are loss-of-function mutations that lead to reduced functional I_{Kr} channel expression or to alterations in channel processing or trafficking.⁴

KvLQT1 alpha subunits associate with minK accessory subunits to form functional channels that resemble slowly activating, noninactivating K⁺ currents, referred to as I_{Ks}, in human myocardium. Mutations in the minK-encoding gene *KCNEL* are associated with LQT5 syndrome. Mutations in the gene encoding KvLQT1 alpha subunits, *KCNQ1*, have been linked to LQT1 syndrome. These mutations are all loss-of-function mutations that result in reduced expression of functional I_{Ks} channels in the outer membrane. Two single-site mutations that cause familial AF are located on adjacent amino acid residues in the first membrane-spanning segment of KCNQ1 and lead to altered physical interactions with the KCNE1 subunits, which ultimately results in slowing of deactivation of I_{Ks} channels.⁵

Kv1.5 alpha subunits contribute to K⁺-selective channels with time- and voltage-dependent characteristics that resemble the rapidly activating and slowly inactivating I_{Kur} in human atrial myocytes. I_{Kur} densities are markedly downregulated in the atria of patients with chronic AF.

Small-conductance, Ca²⁺-sensitive K⁺ channels are tetrameric assemblies of SK alpha subunits and underlie a Ca²⁺-activated K⁺ current, I_{KCa}, in human cardiomyocytes.⁶

Inwardly Rectifying Cardiac K⁺ (Kir) Channels

Kir channels in cardiac myocytes, as in other cells, conduct inward current at membrane potentials negative to E_K and smaller outward currents at membrane potentials positive to E_K. The activity of Kir channels is a function of both membrane potential and the extracellular K⁺ concentration ([K⁺]_o). As [K⁺]_o changes, the channel conducts inward current at potentials negative to the new E_K, whereas a small outward current within a certain potential range positive to the new E_K remains. Inwardly rectifying K⁺ channels are formed by inward rectifier K⁺ channel pore-forming alpha subunits (see Fig. 33-11). In contrast to Kv alpha subunits, Kir alpha subunits have only two (not six) transmembrane domains (see Fig. 33-11). Molecular studies have provided direct evidence that the alpha subunits of the Kir2 subfamily (Kir2.1 and Kir2.2) encode the strongly inwardly rectifying Kir channel I_{K1} in cardiomyocytes.

In cardiomyocytes, Kir6.2 alpha subunits assemble with sulfonylurea receptor proteins to form K⁺-selective sarcolemmal I_{K,ATP} channels. I_{K,ATP} channels are thought to play a pivotal role in myocardial ischemia and preconditioning. For example, opening of cardiac sarcolemmal I_{K,ATP} channels underlies electrocardiographic ST-segment elevation during acute myocardial ischemia. Drugs such as nicorandil and diazoxide open adenosine triphosphate (ATP)-sensitive K⁺ channels, whereas sulfonylurea compounds (such as glibenclamide) inhibit the activity of I_{K,ATP}.

The molecular basis of the acetylcholine-activated K⁺ channel I_{K,ACh} is a heteromultimer of two inwardly rectifying potassium channel subunits, Kir3.1 and Kir3.4. Stimulation of I_{K,ACh} by vagally secreted acetylcholine decreases spontaneous depolarization in the sinoatrial node and slows the velocity of conduction in the AV node. Adenosine, through type 1 purinergic receptor-mediated G protein activation, also increases I_{K,ACh} activity in atrial, sinoatrial node, and AV node cells, thus making this compound a treatment of choice for AV reentry tachycardia.

Cardiac Pacemaker Channel

Channels underlying the pacemaker ("funny") current I_f of sinoatrial myocytes are encoded by the HCN channel gene family. Of the four known HCN pore-forming alpha subunits, HCN4 is the most highly expressed in the mammalian myocardium. A mutation in the human HCN4 gene has been linked to familial sinus bradycardia.⁷

GUIDELINES, 676

In managing clinical arrhythmias, physicians must evaluate and treat the whole patient, not just the rhythm disturbance.¹ Some arrhythmias are hazardous to the patient, regardless of the clinical setting (e.g., ventricular fibrillation [VF]), whereas others are hazardous because of the clinical setting (e.g., rapidly conducted atrial fibrillation [AF] in a patient with severe coronary artery stenoses). Some rhythm abnormalities, such as premature ventricular complexes (PVCs), may be highly symptomatic but not associated with any adverse outcomes, whereas some patients with AF have no symptoms at all but may still be at significant risk for stroke. Evaluation of the patient begins with a careful history and physical examination and should usually progress from the simplest to the most complex test, from the least invasive and safest to the most invasive and risky, and from the least expensive out-of-hospital evaluations to those that require hospitalization and sophisticated, costly, and potentially risky procedures. On occasion, depending on the clinical circumstances, the physician may wish to proceed directly to an expensive procedure associated with some risk, such as an electrophysiologic study (EPS), before obtaining a 24-hour electrocardiographic recording. In most cases, management of arrhythmia has a dual purpose: evaluation and treatment must address not only the patient's symptoms but also whatever risks that the arrhythmia poses to the individual.

HISTORY

Patients with disturbances in cardiac rhythm can have various complaints, but symptoms such as palpitations, syncope, presyncope, or dyspnea commonly cause them to seek a physician's help. Their awareness of palpitations and a regular or irregular cardiac rhythm varies greatly. Some patients perceive slight variations in their heart rhythm with uncommon accuracy, whereas others are oblivious to even sustained episodes of ventricular tachycardia (VT); still others complain of palpitations when they actually have regular sinus rhythm.

In assessing a patient with a known or suspected arrhythmia, several key pieces of information should be obtained that can help determine a diagnosis or guide further diagnostic testing. The *mode of onset* of an episode may provide clues about the type of arrhythmia or preferred treatment option. For example, palpitations that occur in the setting of exercise, fright, or anger are often caused by catecholamine-sensitive automatic or triggered tachycardias that may respond to adrenergic blocking agents (see Chapter 35); palpitations that occur at rest or that awaken the patient may be caused by vagal initiation, such as AF. Lightheadedness or syncope occurring in the setting of a tightly fitting collar, shaving the neck, or turning the head suggests carotid sinus hypersensitivity. The triggering event

may help establish the presence of an inherited ion channel abnormality (see Chapter 32). The *mode of termination* of episodes can also be helpful: palpitations that are reliably terminated by breath-holding or by Valsalva or other vagal maneuvers probably involve the atrioventricular (AV) node as an integral part of a tachycardia circuit; on occasion, focal atrial tachycardias or VTs can be terminated with vagal maneuvers. Patients should be asked about the frequency and duration of episodes and the severity of symptoms. In some women the features of their episodes vary according to the menstrual cycle. These features can help guide how aggressively and quickly the physician needs to pursue a diagnostic or therapeutic plan (a patient with daily episodes associated with near-syncope or severe dyspnea warrants a more expeditious evaluation than does one with infrequent episodes of mild palpitations and no other symptoms). Patients can sometimes report their heart rate during an episode (either rapid or slow, regular or irregular) by counting the pulse directly or by using an automatic blood pressure or heart rate monitor or smart phone application. Characteristics of the mode of onset and frequency of episodes can guide the choice of diagnostic tests (see later).

A careful drug and dietary history should also be sought; some nasal decongestants can provoke tachycardia episodes, whereas beta-adrenergic blocking eye drops for the treatment of glaucoma can drain into tear ducts, be absorbed systemically, and precipitate syncope secondary to bradycardia. Dietary supplements, particularly those containing stimulants such as ephedrine, can cause arrhythmias. A growing list of drugs can directly or indirectly affect ventricular repolarization and produce or exacerbate long-QT interval–related tachyarrhythmias (see Chapter 9; see also www.crediblemeds.org). The patient should be questioned about the presence of systemic illnesses that may be associated with arrhythmias, such as chronic obstructive pulmonary disease, thyrotoxicosis (see Chapter 81), pericarditis (see Chapter 71), and chronic heart failure (see Chapters 24 and 25), as well as previous chest injury, surgery, or radiation therapy or chemotherapy. A family history of rhythm disturbances is often present in those with long-QT syndrome, AF or other inherited arrhythmia syndromes, hypertrophic cardiomyopathy (see Chapter 66), and muscular or myotonic dystrophy (see Chapter 87).

PHYSICAL EXAMINATION

Examination of a patient during an arrhythmia episode can be revealing. Heart rate and blood pressure should be evaluated, as well as how ill the person appears. Assessment of jugular venous pressure and waveform can disclose the rapid oscillations of atrial flutter or “cannon” A waves indicative of contraction of the right atrium against

a closed tricuspid valve in patients with AV dissociation in disorders such as complete heart block or VT. Variations in the intensity of the first heart sound and systolic blood pressure have the same implications.

Physical maneuvers during tachycardia can have diagnostic and therapeutic value. As noted, the Valsalva maneuver² (as well as carotid sinus massage) causes a transient increase in vagal tone; tachyarrhythmias that depend on the AV node for continuation can terminate or slow with these maneuvers but may also show no change. Even though focal atrial and VTs occasionally terminate in response to vagal stimulation, sinus tachycardia slows slightly but returns to its original rate soon thereafter; the ventricular response during atrial flutter and fibrillation and other atrial tachycardias can decrease briefly. During wide-QRS tachycardias with a 1:1 relationship between P waves and QRS complexes, vagal influence can terminate or slow a supraventricular tachycardia (SVT) that depends on the AV node for perpetuation; on the other hand, vagal effects on the AV node can transiently block retrograde conduction and thus establish the diagnosis of VT by demonstrating AV dissociation. Because the effect of either of these physical maneuvers typically lasts only seconds, clinicians must be ready to observe or record any changes in rhythm on an electrocardiogram (ECG) when the maneuver is performed or the response may not be appreciated.

Carotid massage is performed with the patient supine and comfortable and the head tipped away from the side being stimulated. Careful auscultation for carotid bruits must always precede any attempt at carotid massage (embolic events have been associated with massage³). The area of the carotid sinus, at the artery's bifurcation, is palpated with two fingers at the angle of the jaw until a good pulse is felt. Even this minimal amount of pressure can induce a hypersensitive response in susceptible individuals. If no initial effect is noted, a side-to-side or rotating motion of the fingers over the site is performed for up to 5 seconds. A negative response is lack of effect on the ECG after 5 seconds of pressure adequate to cause mild discomfort. Because responses to carotid massage may differ on the two sides, the maneuver can be repeated on the opposite side; however, both sides should never be stimulated simultaneously. Findings may not be readily reproducible, even within minutes of a prior attempt.

Physical findings can suggest the presence of structural heart disease (and thus generally a clinically more serious situation with a worse overall prognosis), even in the absence of an arrhythmia episode. For example, a laterally displaced or dyskinetic apical impulse, a regurgitant or stenotic murmur, or a third heart sound in an older adult can denote significant myocardial or valvular dysfunction or damage.

ELECTROCARDIOGRAM

The ECG is the primary tool for analysis of arrhythmias (see Chapter 12); an EPS, in which intracardiac catheters are used to record activity from several regions of the heart at one time, is more definitive but not always immediately available. Initially, a 12-lead ECG is recorded. In addition, a long continuous recording with use of the lead that shows distinct P waves is often helpful for closer analysis; typically, this is one of the inferior leads (2, 3, aVF), V₁, or aVR. The ECG obtained during an arrhythmia episode may be diagnostic by itself and obviate the need for further diagnostic testing. **Figure 34-1** depicts an algorithm for the diagnosis of specific tachyarrhythmias from the 12-lead ECG (see Chapter 37). A major branch point in the differential diagnosis concerns the QRS duration: wide-QRS (>0.12 second) tachycardias are often VTs, and narrow-QRS (≤0.12 second) tachycardias are almost always SVTs, but there is some overlap (**Table 34-1**). Next, the most important questions to answer, regardless of QRS width, concern the characteristics of P waves. If P waves are not clearly visible on the regular ECG, atrial activity can occasionally be discerned by placing the right and left arm leads in various anterior chest positions (so-called Lewis leads), by recording atrial

TABLE 34-1 Electrocardiographic Distinctions for Diagnosis of Wide-QRS Complex Tachycardia

FAVOR SUPRAVENTRICULAR TACHYCARDIA	FAVOR VENTRICULAR TACHYCARDIA
Initiation with a premature P wave	Initiation with a premature QRS complex
Tachycardia complexes identical to those in resting rhythm	Tachycardia beats identical to PVCs during sinus rhythm
"Long-short" sequence preceding initiation	"Short-long" sequence preceding initiation
Changes in the P-P interval preceding changes in the R-R interval	Changes in the R-R interval preceding changes in the P-P interval
QRS contours consistent with aberrant conduction (V ₁ , V ₆)	QRS contours inconsistent with aberrant conduction (V ₁ , V ₆)
Slowing or termination with vagal maneuvers	AV dissociation or other non-1:1 AV relationship
Onset of the QRS to its peak (positive or negative) <50 msec	Onset of the QRS to its peak (positive or negative) ≥50 msec
	Fusion beats, capture beats
QRS duration ≤0.14 sec	QRS duration >0.14 sec
	Left axis deviation (especially −90° to 180°)
	Concordant R wave progression pattern
	Contralateral bundle branch block pattern from the resting rhythm
	Initial R, q, or r >40 msec or notched Q in aVR
	Absence of an "rS" complex in any precordial lead

electrograms using intracardiac right atrial recordings (via permanent or temporary transvenous pacing leads), or by using esophageal electrodes or an echocardiogram; the last methods are not readily available in most clinical situations and consume valuable time when dealing with a sick patient. A long rhythm strip can usually be obtained and may yield important clues by revealing P waves if perturbations occur during the arrhythmia (e.g., changes in rate, premature complexes, sudden termination, and effect of physical maneuvers, as noted earlier).

Each arrhythmia should be approached in a systematic manner to answer several key questions; as suggested earlier, many of these questions relate to P wave characteristics and underscore the importance of assessing the ECG carefully for them. If P waves are visible, are the atrial and ventricular rates identical? Are the P-P and R-R intervals regular or irregular? If irregular, is it a consistent, repeating irregularity? Is there a P wave related to each QRS complex? Does the P wave seem to precede (long RP interval) or follow (short RP interval) the QRS complex (**Fig. 34-2**)? Are the resultant RP and PR intervals constant? Are all P waves and QRS complexes identical? Is the P wave vector normal or abnormal? Are P, PR, QRS, and QT durations normal? Once these questions have been addressed, one needs to assess the significance of the arrhythmia in view of the clinical setting. Should it be treated, and if so, how? For SVTs with a normal QRS complex, a branching decision tree such as that shown in **Figure 34-1** may be useful.⁴

The Ladder Diagram

A ladder diagram, derived from the ECG, is used to depict depolarization and conduction schematically to aid in understanding the rhythm. Straight or slightly slanting lines drawn on a tiered framework beneath an ECG represent electrical events occurring in the various

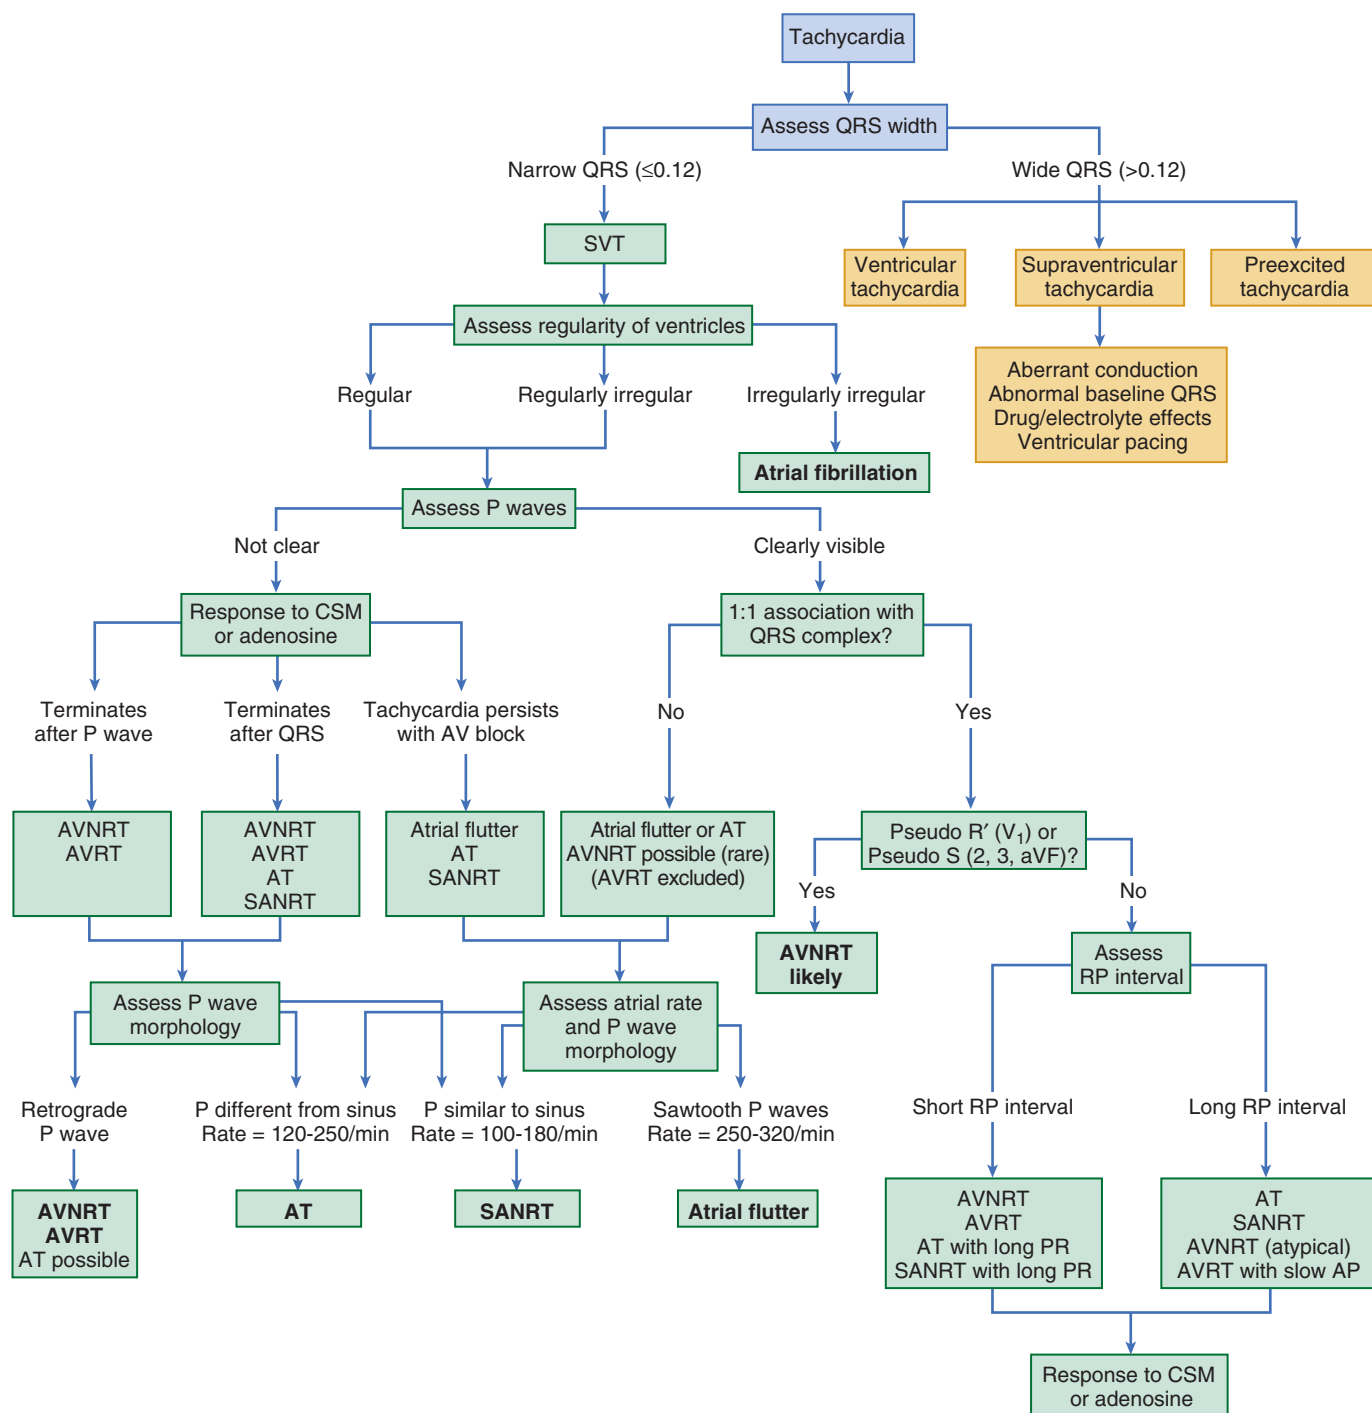

FIGURE 34-1 Stepwise approach to diagnosis of the type of tachycardia based on a 12-lead ECG during the episode. The initial step is to determine whether the tachycardia has a wide or narrow QRS complex. For wide-complex tachycardia, see Table 34-1; the remainder of the algorithm is helpful in diagnosis of the type of narrow-complex tachycardia. AP = accessory pathway; AT = atrial tachycardia; AVNRT = atrioventricular nodal reentrant tachycardia; AVRT = atrioventricular reciprocating tachycardia; CSM = carotid sinus massage; SANRT = sinoatrial nodal reentry tachycardia.

cardiac structures (Fig. 34-3). Because the ECG and therefore the ladder diagram represent electrical activity against a time base, conduction is indicated by the lines of the ladder diagram sloping in a left-to-right direction. A steep line represents rapid conduction; more slanting lines depict slower conduction. A short bar drawn perpendicular to a sloping line represents blocked conduction. Activity originating in an ectopic site such as the ventricle is indicated by lines emanating from that tier. Sinus nodal discharge and conduction and, under certain circumstances, AV junctional discharge and conduction can only be inferred; their activity is not directly recorded on the ECG.

ADDITIONAL TESTS

Most patients have only occasional episodes of arrhythmia and spend most of the time in their baseline rhythm (e.g., sinus, AF). The ECG during the patient's resting rhythm can provide clues about the presence of a substrate for arrhythmia (i.e., structural or physiologic abnormalities from which arrhythmias can arise). Several of these abnormalities are shown in Figure 34-4. Recently, the common finding on the ECG of early repolarization (in the lateral precordial and inferior leads) has been observed in some patients with primary VF (i.e., without identifiable structural heart disease). In most patients

FIGURE 34-2 Differential diagnosis of different types of SVT based on timing of atrial activity (RP and PR intervals). **Left**, Normal beat. Different types of tachycardia are listed below the representative electrocardiographic patterns that they can produce, as categorized by P wave position relative to the QRS complex. An arrowhead shows the location of the P wave in each example. Diagnoses in parentheses are rare causes of the noted findings. AP = accessory pathway.

FIGURE 34-3 Intracardiac signals and ladder diagrams. **A**, A single beat is shown with accompanying intracardiac signals from the sinus node, right atrium, AV nodal and His bundle regions, and right ventricle. **B**, The same beat is shown with the accompanying ladder diagram below. Cardiac regions have been divided into tiers separated by horizontal lines. Vertical dotted lines denote onset of the P wave and QRS complexes. Note the relatively steep lines (rapid conduction through the atrium, His bundle, and ventricular muscle) and more gently sloping lines as the impulse traverses the sinus and AV nodes (signifying slow conduction). **C**, Several different situations are depicted with accompanying explanatory ladder diagrams. Beat 1 is normal, as in **B**; beat 2 shows first-degree AV delay, with the more gradual slope than normal in the AV nodal tier signifying very slow conduction in this region. In beat 3, an atrial premature complex is shown (starting in the atrial tier at the asterisk) and is producing an inverted P wave on the ECG. In beat 4, an ectopic impulse arises in the His bundle (asterisk) and propagates to the ventricle, as well as retrogradely through the AV node to the atrium. In beat 5, a ventricular ectopic complex (asterisk) conducts retrogradely through the His bundle and AV node and eventually to the atrium. **D**, A Wenckebach AV cycle (type I second-degree block) is shown. As the PR interval progressively increases from left to right in the figure, the slope of the line in the AV nodal region is progressively less steep until it fails to propagate at all after the fourth P wave (small line perpendicular to the sloping AV nodal conduction line), after which the cycle repeats. A = atrial recording; H = His recording; V = ventricular recording.

FIGURE 34-4 Electrocardiographic abnormalities in resting rhythm that suggest potential for arrhythmia. Lead V₁ is shown in each example; a normal complex is presented at the left for reference. CM = cardiomyopathy; RBBB = right bundle branch block; RV = right ventricular.

with SVT (aside from those with Wolff-Parkinson-White syndrome), findings on the resting ECG are normal. This is also true for many patients with ventricular tachyarrhythmias. Thus although it is capable of showing an abnormality with possible arrhythmic implications, the resting ECG is not a very sensitive tool. In light of this, the following additional tests can be used to evaluate patients who have cardiac arrhythmias. The physician's choice of which test to use depends on the clinical circumstances. For example, a patient with multiple daily episodes of presyncope is likely to have an event recorded on a 24-hour ambulatory electrocardiographic (Holter) monitor, whereas in a patient who complains of infrequent exercise-induced palpitations, exercise stress testing may be more likely to provide a diagnosis.

Exercise Testing

Exercise can induce various types of supraventricular and ventricular tachyarrhythmias and, uncommonly, bradyarrhythmias (see [Chapter 13](#)). Ventricular ectopy develops in approximately a third of normal subjects in response to exercise testing. Ectopy is more likely to occur at faster heart rates, usually in the form of occasional PVCs of constant morphology or even pairs of PVCs, and is often not reproducible from one stress test to the next. Three to six beats of nonsustained VT can occur in normal patients, especially the elderly, and its occurrence does not establish the existence of ischemic or other forms of heart disease or predict increased cardiovascular morbidity or mortality. PVCs are often more common during exercise than at rest and increase in frequency with age; their occurrence does not imply the presence of structural heart disease. A persistent elevation in heart rate after the end of exercise (delay in return to baseline) is associated with a worse cardiovascular prognosis.

PVCs develop in approximately 50% of patients with coronary artery disease in response to exercise testing. Ventricular ectopy appears in these patients at lower heart rates (<130 beats/min) than in the normal population and often occurs in the early recovery period as well. Frequent (>7 PVCs/min) or complex ectopy is associated with a worse prognosis. Exercise reproduces sustained VT or VF in less than 10% of patients with spontaneous VT or VF late after myocardial infarction, and these patients have a worse prognosis. The relationship of exercise to ventricular arrhythmia in patients with structurally normal hearts has no prognostic implications.

Patients who have symptoms consistent with an arrhythmia induced by exercise (e.g., syncope, sustained palpitations) should be considered for stress testing. Stress testing may be indicated to provoke supraventricular and ventricular arrhythmias, to determine

the relationship of the arrhythmia to activity, to aid in choosing antiarrhythmic therapy and uncovering proarrhythmic responses, and possibly to provide some insight into the mechanism of the tachycardia. The test can be performed safely; however, prolonged ambulatory recording is more sensitive than exercise testing in detecting most arrhythmias. Because either technique can uncover serious arrhythmias that the other technique misses, both examinations may be indicated for selected patients. Stress testing is frequently useful in patients with long-QT syndrome and catecholaminergic VT (see [Chapters 13 and 32](#)).⁵

In-Hospital Electrocardiographic Recording

Electrocardiographic monitoring systems are used in increasing proportions of inpatients regardless of history or suspicion of arrhythmias. These systems can provide valuable information about rhythm abnormalities, including mode of onset and termination, and allow prompt acquisition of a full 12-lead ECG for more detail. Telemetry may disclose intermittent heart block in a patient with presyncope that may warrant consideration of pacemaker implantation or reveal nonsustained VT in a patient with previous myocardial infarction and left ventricular dysfunction and prompt an electrophysiology study for further assessment of risk. As often as telemetry is helpful in such cases, however, it can be misleading: artifact can simulate VT or VF, heart block, or asystole. Careful scrutiny is necessary to avoid unnecessary tests and procedures in patients with these artifactual arrhythmias ([Fig. 34-5](#); real and artifact on monitor).

Long-Term Electrocardiographic Recording

Prolonged electrocardiographic recording in patients engaged in normal daily activities is the most useful noninvasive method to document and quantitate the frequency and complexity of an arrhythmia, to correlate the arrhythmia with the patient's symptoms, and to evaluate the effect of antiarrhythmic therapy on spontaneous arrhythmia. For example, recording normal sinus rhythm during the patient's typical symptomatic episode effectively excludes cardiac arrhythmia as a cause. In addition, some recorders can document alterations in QRS, ST, and T contours.

Ambulatory Electrocardiographic (Holter) Recording

Continuous electrocardiographic tape recorders represent the traditional Holter monitor and digitally record three or more electrocardiographic channels for 24 to 48 hours. Computers scan the recording media, with human oversight, to provide a report with snapshot

FIGURE 34-5 Electrocardiographic events and artifacts. **A**, Sinus rhythm punctuated by short episodes of atrial tachycardia with a more rapid ventricular rate (between the white arrows). **B**, Pseudo-atrial arrhythmia. Sinus rhythm is present throughout (no variation in the R-R interval) despite the appearance of a short episode of atrial flutter or fibrillation (between the black arrows). **C**, nonsustained VT (between the white arrows) with wide rapid QRS complexes not preceded by a P wave and seen in two monitor leads. **D**, Pseudo-VT. Despite the appearance of VT (between the black arrows), sinus rhythm is present throughout (including complexes indicated by asterisks). **E**, Pseudo-pacemaker failure. After the first five paced complexes, the ECG is flat in both monitor leads, thus suggesting failure of pacemaker output; however, the pulse contour on the blood pressure (BP) tracing indicates that the heart is still contracting and the pacemaker is still working whereas the ECG monitor is not.

recordings of symptomatic events and other important findings (asymptomatic arrhythmias, ST-segment changes). All systems can potentially record more information than the physician needs or can assimilate. As long as the system detects important episodes of ectopic activity, VT, or asystolic intervals and semiquantitates these abnormalities, the physician probably receives all the clinical information that is needed. Twenty-five percent to 50% of patients experience a complaint during a 24-hour recording; in 2% to 15% the complaint is caused by an arrhythmia (Fig. 34-6). The ability to correlate symptoms temporally with abnormalities on the ECG is one of the strengths of this technique.

Significant rhythm disturbances are uncommon in healthy young persons. Sinus bradycardia with heart rates of 35 to 40 beats/min, sinus arrhythmia with pauses exceeding 3 seconds, sinoatrial exit block, type I (Wenckebach) second-degree AV block (often during sleep), wandering atrial pacemaker, junctional escape complexes, and premature atrial complexes and PVCs can be observed and are not necessarily abnormal. Frequent and complex atrial and ventricular rhythm disturbances are less commonly observed, however, and type II second-degree AV conduction disturbances (see Chapter 37) are not recorded in normal patients. Elderly patients (see Chapter 76) have a higher prevalence of arrhythmias, some of which may be responsible for neurologic symptoms (Fig. 34-7; also see Chapter

87). The long-term prognosis in asymptomatic healthy subjects with frequent and complex PVCs usually resembles that of the healthy U.S. population, without an increased risk for death. However, frequent PVCs (>15% of the total) have recently been shown to produce cardiomyopathy and heart failure in some people, which can be reversed following elimination of the PVCs.

Most patients with ischemic heart disease, particularly after myocardial infarction (see Chapters 51 and 52), exhibit PVCs when they are monitored for 24 hours. The frequency of PVCs progressively increases during the first several weeks and then decreases at about 6 months after infarction. Frequent and complex PVCs are associated with a twofold to fivefold increased risk for cardiac or sudden death in patients after myocardial infarction, but treating these PVCs may not improve the prognosis. CAST (Cardiac Arrhythmia Suppression Trial) showed that PVCs identified patients at increased risk for sudden death but that successful suppression of PVCs with flecainide, encainide, or moricizine was associated with increased mortality in comparison to placebo. Recent data indicate that ablation of PVCs after myocardial infarction may improve previously depressed ventricular function.

Long-term recording of the ECG has also exposed potentially serious arrhythmias and complex ventricular ectopy in patients with left ventricular hypertrophy, as well as in those with hypertrophic, dilated, and ischemic cardiomyopathy; in those with mitral valve prolapse (see Chapter 63); in those with otherwise unexplained syncope (see Chapter 40) or transient vague cerebrovascular symptoms; and in those with conduction disturbances, sinus node dysfunction, bradycardia-tachycardia syndrome, Wolff-Parkinson-White syndrome (see Chapter

37), and pacemaker malfunction (see Chapter 36). It has been shown that asymptomatic AF occurs far more often than symptomatic episodes in patients with AF.

Variations of Holter recording have been used for particular applications. Some monitoring systems are able to reconstruct a full 12-lead ECG from a 7-electrode recording system. This is especially useful in trying to document the electrocardiographic morphology of VT before an ablation procedure or a consistent morphology of PVCs that may arise from an ablatable focus of VT or VF. Most Holter recording and analysis systems can place a clearly recognizable deflection on the recording when a pacemaker stimulus is detected. This greatly facilitates diagnosis of potential pacemaker malfunction. On occasion, artifacts on the ECG caused by alterations in tape recording or playback speed can mimic bradycardias or tachycardias and lead to erroneous therapy. Newer digital Holter systems are less subject to this phenomenon. Finally, most systems can also provide heart rate variability and QT data (see later). Use of these systems for detection of myocardial ischemia (ST-segment analysis) has yielded mixed results (in both specificity and sensitivity).

Event Recording

In many patients, the 24- or 48-hour snapshot provided by the Holter recording is incapable of documenting the cause of the patient's

FIGURE 34-6 Long-term electrocardiographic recording in a patient with palpitations. A three-channel monitor shows sinus rhythm followed by nine wide QRS complexes of VT (labeled "V"); the complex that precedes these is a fusion between the normal complex and wide ("F"). Arrows indicate retrograde P waves during tachycardia. The presence of fewer P waves than QRS complexes and a fusion complex at the outset confirm the diagnosis of VT (which correlated with the patient's palpitations).

FIGURE 34-7 Continuous electrocardiographic recording from a patient-activated event monitor during an episode of lightheadedness. Sinus rhythm at 75 beats/min with sudden AV block is present with pauses of longer than 4 seconds, and in the bottom strip there is an effective heart rate of approximately 8 beats/min.

symptoms. Longer-term monitoring, such as with an event recorder, is necessary in these cases, which occur frequently. These devices are about the size of a pager and are kept by the patient for 30 days. During that time, digital recordings can be made during symptomatic episodes and be transmitted to a receiving station over standard telephone lines at the patient's convenience (see Fig. 34-7). Some of these recorders store more than 30 seconds of the ECG before the patient activates the recording. These loop recorders record continuously, but only a small window of time is present in memory at any moment; when the event button is pressed by the patient, the current window is frozen while the device continues recording for another 30 to 60 seconds, depending on how it is configured. Event recorders are highly effective in documenting infrequent events, but the quality of the recordings is more subject to motion artifact than with Holter recorders, and usually only one channel can be recorded. With some systems the patient must be able to press the event button to begin recording; if syncope occurs without warning and the patient is not able to actuate the device, it cannot provide diagnostic information. With other systems, the device automatically begins recording the rhythm when the heart rate increases or decreases outside preset parameters. Some systems incorporate cell phone technology that automatically notifies a central monitoring facility when certain conditions are met (e.g., extreme bradycardia or tachycardia). In this way the time between occurrence and effective treatment of serious arrhythmias can be significantly shortened.⁶

Most currently available pacemakers and implantable defibrillators are capable of providing Holter-like data when premature beats or tachycardia episodes occur and can store electrograms of these events from the implanted leads.⁷ The device can then be interrogated and the electrograms printed for analysis. Many implanted device systems incorporate remote monitoring so that if symptoms develop, patients can perform device interrogation at home; the information is then transmitted via the Internet to the physician's office and thus enables more prompt diagnosis and treatment than if the patient had to schedule an outpatient visit.

Implantable Loop Recorder

For patients with very infrequent symptoms, neither Holter recorders nor 30-day event recorders may yield diagnostic information. In such patients, an implantable loop recorder may be used. This device (about the size of a pack of chewing gum) is inserted under the skin at about the second rib on the left front aspect of the chest and is activated by passing a special magnet over the device. It is capable of recording up to 42 minutes of a single channel of the ECG that can be partitioned for one to seven episodes, with up to 20 minutes of the preactivation ECG being saved for subsequent downloading to a programming unit for analysis. Both P waves and QRS complexes can usually be identified. The device can be configured to store patient-activated episodes, automatically activated recordings (heart rate outside preset parameters), or a combination of these. In one report of patients with unexplained syncope, a

diagnosis was ultimately made in 80% by long-term monitoring, in 26% of them after 18 months of monitoring.⁸

A variety of additional noninvasive tests have been developed primarily to assess the risk for arrhythmic death in different groups of patients; although each has some applicability, none has enjoyed widespread use because of suboptimal sensitivity and specificity. Several of these tests are discussed in the following sections.

Heart Rate Variability

Heart rate variability is used to evaluate vagal and sympathetic influences on the sinus node (inferring that the same activity is also occurring in the ventricles) and to identify patients at risk for a cardiovascular event or death.⁹ Frequency domain analysis resolves parasympathetic and sympathetic influences better than time domain analysis does, but both types of analysis are useful. R-R variability predicts all-cause mortality, as well as left ventricular ejection fraction or nonsustained VT in patients after myocardial infarction, and can be added to other measures of risk to enhance predictive accuracy. Similar results have been obtained in patients with dilated cardiomyopathy (see Chapters 25 and 65). High-frequency components of R-R interval variability reflect tonic vagal activity. Reduced R-R interval variability, a marker of increased risk, indicates loss or reduction of the physiologic periodic sinus node fluctuations, which has many potential causes and may not necessarily represent a significant shift in autonomic modulation. New indices of heart rate variability are continually being evaluated. Even the simple measure of resting heart rate has been shown to be an independent cardiovascular risk factor, although

a target “safe” heart rate has not been established, as has the heart rate obtained during and after exercise.

Heart Rate Turbulence

Heart rate turbulence is an index of changes in the sinus discharge rate after a PVC that is followed by a compensatory pause.¹⁰ In normal individuals, the sinus rate initially accelerates and then slows; this phenomenon is blunted or absent in patients with various heart diseases. Heart rate turbulence is a measure of reflex vagal control of the heart, whereas heart rate variability is more indicative of overall vagal tone. Abnormal heart rate turbulence is a strong independent predictor of mortality in patients with coronary artery disease and dilated cardiomyopathy; abnormal indices in some patients can be improved or normalized after treatment with beta blockers and statin drugs.

QT Dispersion

Heterogeneity in refractoriness and conduction velocity is a hallmark of reentrant arrhythmias. One index of the heterogeneity of ventricular refractoriness can be found in differences in the length of the QT interval on surface leads of the ECG. The index most commonly used to calculate this QT dispersion has been the difference between the longest and shortest QT intervals on the 12-lead ECG, which is often adjusted for heart rate and the number of leads sampled (when the T wave is flat in some). Other indices have also been developed. Abnormally high QT dispersion has been correlated with risk for arrhythmic death in patients with various disorders, although the results are not consistent. Its mechanism has been characterized in several disease states. QT dispersion has been correlated with both efficacy and the proarrhythmic potential of drug therapy. Different techniques exist for determining dispersion (including automated algorithms), and the results of one study are often difficult to compare with those of another; in addition, the test is sensitive to age, time of day, season of year, and even body position.¹¹ Overall, assessment of QT dispersion has not gained popularity as a useful clinical tool.

Signal-Averaged Electrocardiography and Late Potentials

Signal averaging is a method that improves the signal-to-noise ratio when the signals are recurrent and the noise is random. In conjunction with appropriate filtering and other methods of noise reduction, signal averaging can detect cardiac signals of a few microvolts in amplitude and reduce noise amplitude, such as muscle potentials, which are typically 5 to 25 mV, to less than 1 mV. With this method, very low-amplitude electrical potentials generated by the sinus and AV nodes, His bundle, and bundle branches are detectable at the body surface.

One constituent of reentrant ventricular arrhythmias in patients with previous myocardial damage is slow conduction. Direct cardiac mapping techniques can record the myocardial activation from damaged areas that occurs after the end of the surface electrocardiographic QRS complex during sinus rhythm. These delayed signals have a very low amplitude that cannot be discerned by routine electrocardiography and correspond to the delayed and fragmented conduction in the ventricles recorded with direct mapping techniques (Fig. e34-1). Signal averaging has been applied clinically most often to detect such late ventricular potentials of 1 to 25 mV. Criteria for late potentials are the following: (1) filtered QRS complex duration longer than 114 to 120 milliseconds, (2) less than 20 mV of the root mean square signal amplitude in the last 40 milliseconds of the filtered QRS complex, and (3) terminal filtered QRS complex remaining below 40 mV for longer than 39 milliseconds. Such late potentials have been recorded in more than 70% of patients with spontaneous sustained and inducible VT after myocardial infarction but in only 0% to 6% of normal volunteers. Late potentials can be detected as early as 3 hours after the onset of coronary artery occlusion, increase in prevalence in the first week after myocardial infarction, and disappear in some patients after 1 year. If they are not present initially, late potentials do not usually appear later. Patients with bundle branch block or paced ventricular rhythms already have wide QRS complexes, thus rendering the technique less useful in these cases.

Late potentials have also been recorded in patients with VT not related to ischemia, such as in those with dilated cardiomyopathy. The presence of a late potential is a sensitive but not specific marker of arrhythmic risk, and therefore its prognostic use is limited. In specific situations it can be helpful, for example, in a patient suspected of having arrhythmogenic right ventricular cardiomyopathy¹² or a patient with a previous inferior wall myocardial infarction (normally the last portion of the heart to be activated), in whom the absence of a late potential suggests very low risk of having VT episodes.

The high-pass filtering used to record late potentials meeting the criteria just noted is called time domain analysis because the filter output corresponds in time to the input signal. Because late potentials are high-frequency signals, Fourier transform can be applied to extract high-frequency content from the signal-averaged ECG, called frequency domain analysis. Some data suggest that frequency domain analysis provides useful information not available with time domain analysis.

Signal averaging has been applied to the P wave to determine risk for the development of AF (especially after cardiac surgery), as well as maintenance of sinus rhythm after cardioversion.¹³ Overall use of the technique remains limited at present.

T Wave Alternans

Beat-to-beat alternation in the amplitude or morphology of the electrocardiographic recording of ventricular repolarization, the ST segment and T wave, has been found in conditions favoring the development of ventricular tachyarrhythmias, such as ischemia and long-QT syndrome, and in patients with ventricular arrhythmias. The electrophysiologic basis appears to be the alternation of repolarization of ventricular myocytes. In the presence of a long QT interval, the cellular basis of alternation may be beat-to-beat repolarization changes in midmyocardial cells (so-called M cells). Whether this mechanism applies to different disease states is not known. T wave alternans testing requires exercise or atrial pacing to achieve a heart rate of 100 to 120 beats/min with relatively little atrial or ventricular ectopic activity. The test is less useful in patients with a wide QRS complex (>120 milliseconds). A positive T wave alternans test result (Fig. e34-2) has been associated with a worse arrhythmic prognosis in various disorders, including ischemic heart disease and nonischemic cardiomyopathy. Although the predictive value of a positive test result varies greatly, depending on the population studied, a negative test result strongly predicts freedom from VT and VF in all group studied thus far, at least during a short follow-up period. Thus the test's best application appears to be in patients whose arrhythmic risk is equivocal, in whom a negative T wave alternans test result suggests low risk for the development of life-threatening ventricular arrhythmias. T wave alternans testing alone has not helped segregate patients more likely to benefit from implantable cardioverter-defibrillator (ICD) use (positive test result) from those who are not (negative test result) and should therefore not undergo ICD implantation. Both frequency domain (spectral method) and time domain (modified moving average) analyses have usefulness in risk stratification. T wave alternans may represent a fundamental marker of an electrically unstable myocardium prone to the development of VT or VF, but because of its relatively minor incremental value in defining arrhythmic risk, it is not frequently used at present.¹⁴

Baroreceptor Reflex Sensitivity Testing

Acute blood pressure elevation triggers a baroreceptor reflex that augments vagal tone to the heart and slows the sinus rate. The increase in sinus cycle length per millimeter mercury increase in systolic blood pressure is a measure of the sensitivity of the baroreceptor reflex and, when reduced, identifies patients susceptible to the development of VT and VF. The mechanism of the reduction in baroreceptor reflex sensitivity is not certain. However, this test may be useful to identify patients at risk for the development of a serious ventricular arrhythmia after myocardial infarction.

Body Surface Mapping

Isopotential body surface maps are used to provide a complete picture of the effects of currents from the heart on the body surface. The potential distributions are represented by contour lines of equal potential, and each distribution is displayed instant by instant throughout activation, recovery, or both.

Body surface maps have been used clinically to localize and size areas of myocardial ischemia, to localize ectopic foci or accessory pathways, to differentiate aberrant supraventricular conduction from ventricular origin, to recognize patients at risk for the development of arrhythmias, and possibly to understand the mechanisms involved. Although these procedures are of interest, their clinical usefulness has not yet been established. In addition, the technique is cumbersome and the analysis is complex.

FIGURE e34-1 Signal-averaged ECG. Normal (left) and abnormal (right) results are shown from a patient with previous myocardial infarction and VT. **Bottom panels,** Shaded blue areas at the end of each tracing represent the voltage content of the last 40 milliseconds of the filtered QRS integral. The small shaded area (red arrowhead) in the abnormal study denotes prolonged, slow conduction and suggests the potential for reentrant ventricular arrhythmias.

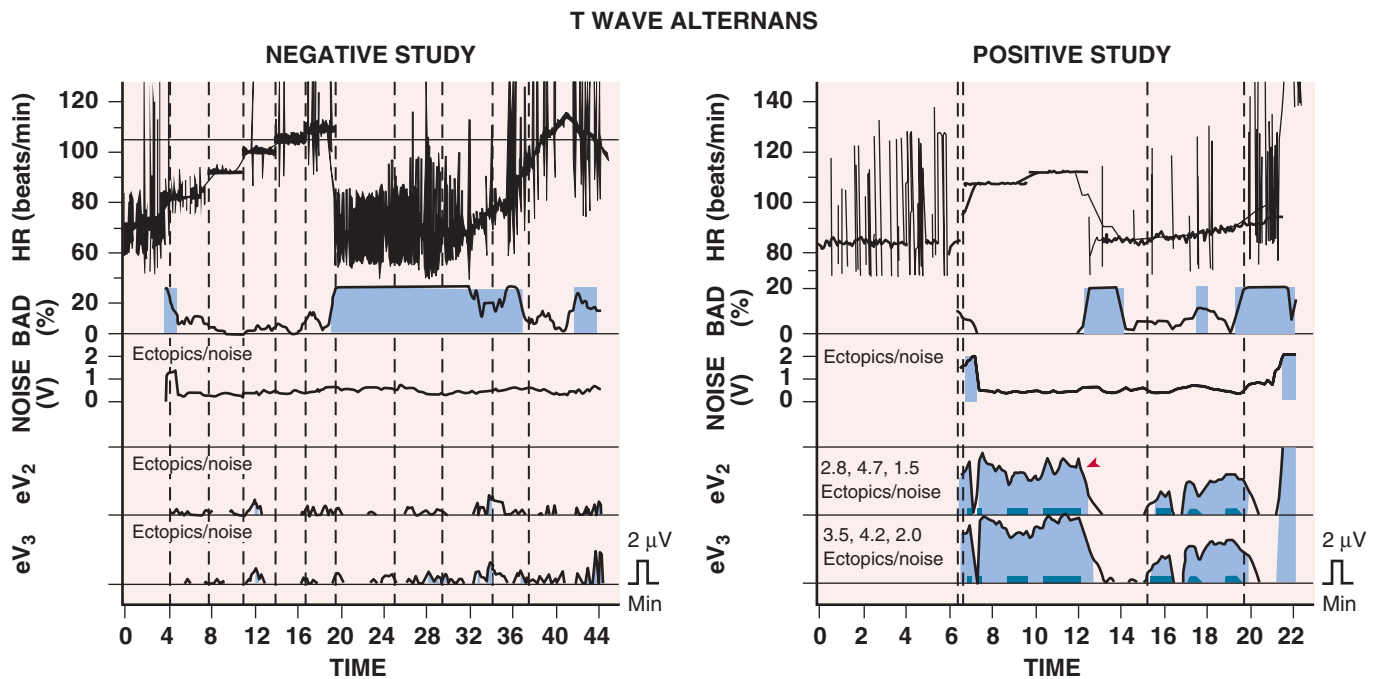

FIGURE e34-2 T wave alternans. Reports of T wave alternans analysis from two patients are shown and display the heart rate in beats/min (HR BPM), proportion of beats rejected from analysis (% BAD), ECG noise level (in microvolts), and selected precordial leads (eV_2 and eV_3) as a function of time. **Left panel,** Records from a patient with no structural heart disease; the amplitude of T wave alternans was minimal. **Right panel,** Records from a patient hospitalized for sustained VT after myocardial infarction show T wave alternans (blue shaded area, arrowhead).

Electrocardiographic Imaging

Another promising technology is electrocardiographic imaging, in which cardiac electrical activity recorded at the skin surface is spatially integrated with imaging data (currently, cardiac computed tomography scanning). Using complex mathematical processing of electrical data collected from 224 electrodes on the skin surface, this technique can plot or project atrial and ventricular electrical activity on an epicardial “shell” of the patient’s own heart and thereby follow the course of activation during sinus rhythm or an arrhythmia. Clinical experience is limited thus far, but both SVTs and VTs have been able to be localized in a variety of settings.¹⁵

Upright Tilt-Table Testing

The tilt-table test is used to identify patients who have a vasodepressor or cardioinhibitory response as a cause of syncope (see Chapter 40). Patients are placed on a tilt table in the supine position and tilted upright to a maximum of 60 to 80 degrees for 20 to 45 minutes or longer if necessary (Fig. e34-3). Isoproterenol, administered as a bolus or infusion, may provoke syncope in patients whose initial upright tilt-table test result shows no abnormalities or, after a few minutes of tilt, may shorten the time needed to produce a positive response on the test. An initial intravenous isoproterenol dose of 1 µg/min can be increased in 0.5-µg/min steps until symptoms occur or a maximum of 4 µg/min is given. Isoproterenol induces a vasodepressor response in upright susceptible patients (decrease in heart rate and blood pressure along with near-syncope or syncope). Tilt-table test results are positive in two thirds to three fourths of patients susceptible to neurally mediated syncope and are reproducible in approximately 80% but have a 10% to 15% false-positive response rate. A positive test result is more meaningful when it reproduces symptoms that have occurred spontaneously. Positive responses can be divided into cardioinhibitory, vasodepressor, and mixed categories. Therapy with beta blockers, disopyramide, theophylline, selective serotonin reuptake inhibitors, midodrine, fludrocortisone, salt loading, and thigh-high support stockings, alone or in combination, has been reported to be successful but not with reliable reproducibility. Tilt training, in which the patient leans against a wall for prolonged periods to increase tolerance to this body position, as well as isometric muscle flexing to abort or lessen an episode, may help. Permanent pacing has been useful in a subset of patients with significant bradycardia.

A variant of the neurocardiogenic response, postural orthostatic tachycardia syndrome (POTS), is characterized by dramatic increases in heart rate during the first 10 minutes of tilt-table testing. POTS appears to be distinct from simple orthostatic hypotension, as well as from standard neurocardiogenic responses, and is thought to be caused by various forms of autonomic imbalance. Relief of symptoms has been effected with fludrocortisone, beta blockers, or combinations.

Esophageal Electrocardiography

Esophageal electrocardiography is a useful noninvasive technique for diagnosing arrhythmias. The esophagus is located immediately behind the left atrium, between the left and right pulmonary veins. An electrode in the lumen of the esophagus can record atrial potentials. Bipolar recording is superior to unipolar recording because far-field ventricular events can lead to possible diagnostic confusion with unipolar recording. In addition, atrial and occasionally ventricular pacing can be performed by means of a catheter electrode inserted into the esophagus, and tachycardias can be initiated and terminated. Optimal electrode position for atrial pacing correlates with the patient’s height and is within about 1 cm of the site at which the maximum amplitude of the atrial electrogram is recorded. When it is recorded simultaneously with the surface ECG, the esophageal atrial electrogram can be used to differentiate SVT with aberrancy from VT and to define the mechanism of SVTs. Complications of transesophageal recording and pacing are uncommon, but the technique is cumbersome and uncomfortable for most patients, and it is therefore not commonly used.

intracardiac sites to record or stimulate cardiac electrical activity. Assessment of AV conduction at rest is done by positioning the catheter along the septal leaflet of the tricuspid valve and measuring the atrial-His interval (an estimate of AV nodal conduction time; normally, 60 to 125 milliseconds) and the His-ventricular (H-V) interval (a measure of infranodal conduction; normally, 35 to 55 milliseconds). The heart is stimulated from portions of the atria or ventricles and from the region of the His bundle, bundle branches, accessory pathways, and other structures. Such studies are performed diagnostically to provide information about the type of clinical rhythm disturbance and insight into its electrophysiologic mechanism. An EPS is used therapeutically to terminate a tachycardia by electrical stimulation or electroschock, to evaluate the effects of therapy by determining whether a particular intervention modifies or prevents electrical induction of a tachycardia or whether an electrical device properly senses and terminates an induced tachyarrhythmia, and to ablate myocardium involved in the tachycardia and prevent further episodes. Finally, these tests have been used prognostically to identify patients at risk for sudden cardiac death. The study may be helpful in patients with AV block, intraventricular conduction disturbance, sinus node dysfunction, tachycardia, and unexplained syncope or palpitations (see Chapter 40).

An EPS is effective at initiating VT and SVT when these tachyarrhythmias have occurred spontaneously. This enables the use of similar stimulation techniques after an intervention (e.g., drug therapy or catheter or surgical ablation) to assess the efficacy of treatment. However, false-negative responses (not finding a particular electrical abnormality known to be present) and false-positive responses (induction of a nonclinical arrhythmia) may complicate interpretation of the results because many lack reproducibility. Altered autonomic tone in a supine patient undergoing study, hemodynamic or ischemic influences, changing anatomy (e.g., new infarction) after the study, day-to-day variability, and the fact that the test uses an artificial trigger (electrical stimulation) to induce the arrhythmia are several of many factors that can explain the occasional disparity between test results and spontaneous occurrence of arrhythmia. Overall, the diagnostic validity and reproducibility of these studies are good, and they are safe when performed by skilled clinical electrophysiologists.

Atrioventricular Block

In patients with AV block, the site of block usually dictates the clinical course of the patient and whether a pacemaker is needed (see Chapter 37). In general, the site of AV block can be determined from analysis of the regular ECG. When the site of block cannot be determined from such an analysis and when knowing the site of block is imperative for management of the patient, an invasive EPS is indicated. Candidates include symptomatic patients in whom a His-Purkinje block is suspected but not established and patients with AV block treated with a pacemaker who continue to be symptomatic and in whom a causal ventricular tachyarrhythmia is suspected. Possible candidates are those with second- or third-degree AV block, for whom information about the site of block or its mechanism may help direct therapy or assess prognosis, and patients suspected of having concealed His bundle extrasystoles. Patients with block in the His-Purkinje system become symptomatic because of periods of bradycardia or asystole and require pacemaker implantation more often than do patients who have AV nodal block. Type I (Wenckebach) AV block in older patients may have clinical implications similar to those for type II AV block. The results of EPS for evaluating the conduction system must be interpreted with caution, however. In rare cases, the process of recording conduction intervals alters their values. For example, catheter pressure on the AV node or His bundle can cause prolongation of the atrial-His or H-V interval and could lead to erroneous diagnosis and therapy.

Intraventricular Conduction Disturbance

For patients with an intraventricular conduction disturbance, an EPS provides information about the duration of the H-V interval, which can be prolonged with a normal PR interval or normal with a

INVASIVE ELECTROPHYSIOLOGIC STUDIES

An invasive EPS involves introducing multipolar catheter electrodes into the venous or arterial system and positioning them at various

FIGURE e34-3 Head-up tilt-table testing. Responses to tilt-table testing are shown; heart rate (HR) and systolic blood pressure (BP) are plotted as time functions. In the **upper panel**, a normal response is an early, slight drop in BP with a compensatory increase in HR mediated by the autonomic nervous system. With autonomic dysfunction, a progressive fall in BP is not counteracted by an increase in HR. In postural tachycardia syndrome, an exaggerated increase in HR is seen. The **bottom panel** depicts findings with neurocardiogenic syncope: a pure vasodepressor response is a relatively sudden drop in BP without a marked change in HR, whereas a pure cardioinhibitory response shows a sudden decrease in HR without a change in BP. A mixed response shows decreases in both HR and BP.

FIGURE 34-8 Testing the His-Purkinje system. A 43-year-old woman with sarcoid underwent EPS after a syncopal episode. Surface leads 1, 2, V_1 , and V_6 are shown, with intracardiac recordings from catheters in the high right atrium (HRA), the proximal (His_{prox}) and distal (His_{dist}) electrode pairs of a catheter at the AV junction to record the His potential, and right ventricular apex (RVA). During baseline recording, the H-V interval is only slightly prolonged (62 milliseconds). After infusion of intravenous procainamide, the H-V interval is longer and an infra-His Wenckebach block is present. The arrowhead denotes the missing QRS complex caused by infra-His block. A = atrial electrogram; H = His potential; V = ventricular electrogram.

prolonged PR interval. A prolonged H-V interval (>55 milliseconds) is associated with a greater likelihood for the development of a trifascicular block (but the rate of progression is slow, 2% to 3% annually) and for having structural disease and with higher mortality.¹⁶ The finding of very long H-V intervals (>80 to 90 milliseconds) identifies patients at increased risk for the development of AV block. The H-V interval has high specificity ($\approx 80\%$) but low sensitivity ($\approx 66\%$) for predicting the development of complete AV block. During the study, atrial pacing is used to uncover abnormal His-Purkinje conduction. A positive response is provocation of distal His block during 1:1 AV nodal conduction at rates of 135 beats/min or less. Again, sensitivity is low but specificity is high. Functional His-Purkinje block caused by normal His-Purkinje refractoriness is not a positive response. Drug infusion, such as with procainamide or ajmaline, sometimes exposes abnormal His-Purkinje conduction (Fig. 34-8). Ajmaline (not available in the United States) can cause arrhythmias and should be used cautiously.

An EPS is indicated in patients with symptoms (syncope or presyncope) that appear to be related to a bradyarrhythmia or tachyarrhythmia when no other cause of symptoms is found. For many of these patients, ventricular tachyarrhythmias rather than AV block can be the cause of their symptoms, with obvious therapeutic implications.

Sinus Node Dysfunction

Demonstration of slow sinus rates, sinus exit block, or sinus pauses temporally related to symptoms suggests a causal relationship and usually obviates further diagnostic studies (see Chapter 37). Carotid sinus pressure that results in several seconds of complete asystole or AV block and reproduces the patient's usual symptoms exposes the presence of a hypersensitive carotid sinus reflex. Carotid sinus massage must be done cautiously; rarely, it can precipitate a stroke. Neurohumoral agents, adenosine, or stress testing can be used to evaluate the effects of autonomic tone on sinus node automaticity and sinoatrial conduction time. An EPS should be considered in patients who have symptoms attributable to bradycardia or asystole, such as presyncope or syncope, and for whom noninvasive approaches have provided no explanation for the symptoms.

Sinus Node Recovery Time.

Sinus node recovery time (SNRT) is a technique that can be useful for evaluating sinus node function. The interval between the last paced high right atrial response and the first spontaneous (sinus) high right atrial response after termination of pacing is measured to determine SNRT. Because the spontaneous sinus rate influences SNRT, the value is corrected by subtracting the spontaneous sinus node cycle length (before pacing) from the SNRT (Fig. 34-9). This value, the corrected SNRT (CSNRT), is generally shorter than 525 milliseconds. A prolonged CSNRT has been found in patients suspected of having sinus node dysfunction. After cessation of pacing, the first return sinus cycle can be normal but can be followed by secondary pauses. Secondary pauses appear to be more common in patients whose sinus node dysfunction is caused by sinoatrial exit block (a potential cause of sinus pauses on the ECG). Direct recordings of the sinus node electrogram have been made, but the technique is cumbersome. Finally, it is important to evaluate AV node and His-Purkinje function in patients with sinus node dysfunction because many also exhibit impaired AV conduction.

Sinoatrial Conduction Time.

Sinoatrial conduction time (SACT) can be estimated by simple pacing techniques based on the assumptions that (1) conduction times into and out of the sinus node are equal, (2) no depression of sinus node automaticity occurs, and (3) the pacemaker site does not shift after premature stimulation (see Chapter 34). These assumptions can be erroneous, particularly in patients with sinus node dysfunction. SACT can also be measured directly with special recording techniques, as noted above, from the region of the sinus node. This direct measurement correlates well with the SACT measured indirectly in patients with normal sinus node function. The sensitivity of the SACT and SNRT tests is only approximately 50% for each test alone and around 65% when they are combined. The specificity, combined, is approximately 88%, with a low predictive value. Thus if these test results are abnormal, the likelihood of the patient having sinus node dysfunction is great. However, normal results do not exclude the possibility of sinus node disease. Candidates for invasive EPS to evaluate sinus node function are symptomatic patients in whom sinus node dysfunction has not been established as a cause of the symptoms. Potential candidates are patients with clinical sinus node dysfunction in whom other causes of symptoms (e.g., tachyarrhythmias) are to be excluded.

Tachycardia

In patients with tachycardias, an EPS can be used to diagnose the arrhythmia, to determine and deliver therapy, to establish the anatomic sites involved in the tachycardia, to identify patients at high risk for the development of serious arrhythmias, and to gain insight into the mechanisms responsible for the arrhythmia (see Chapter 37). The study can differentiate aberrant supraventricular conduction from ventricular tachyarrhythmias when standard electrocardiographic criteria are equivocal.

An SVT is recognized electrophysiologically by an H-V interval equaling or exceeding that recorded during normal sinus rhythm (Fig. 34-10). In contrast, during VT, the H-V interval is shorter than normal or the His deflection cannot be recorded clearly because of superimposition of the larger ventricular electrogram. Only two situations exist in which a consistently short H-V interval occurs: during retrograde activation of the His bundle from activation originating in the ventricle (i.e., PVC, ventricular pacing, or VT) and during AV conduction over an accessory pathway (preexcitation syndrome).

FIGURE 34-9 Abnormal sinus node function. Recordings are similar to those in Figure 34-8. The last five complexes of a 1-minute burst of atrial pacing (S) at a cycle length of 400 milliseconds are shown, after which pacing is stopped. The sinus node does not spontaneously discharge (SNRT) until 6.2 seconds later (arrowhead). Three junctional escape beats occurred before this time. His_{dist} = distal electrode pair; HRA = high right atrium; RVA = right ventricular apex.

FIGURE 34-10 Bundle of His recordings in different situations similar to those in Figures 34-8 and 34-9. **A**, Baseline sinus rhythm with normal AV conduction. **B**, Orthodromic SVT with retrograde conduction over a left-sided accessory pathway throughout the tracing. The first three beats have a narrow QRS complex with a normal H-V interval; the last three QRS complexes represent a fusion of conduction over the AV node–His bundle and a slowly conducting right-sided accessory pathway. The His potential occurs after onset of the wide QRS complex (dashed lines). **C**, Three paced ventricular beats are shown with a retrograde His potential (H'), followed by initiation of AV node reentrant SVT (atrial depolarization near the end of the QRS complex, as seen in the HRA tracing). **D**, VT with delayed activation of the His potential and complete retrograde AV node block (dissociated atrial complexes). CS_{prox} = proximal coronary sinus; His_{dist} = distal electrode pair; His_{prox} = proximal electrode pair; HRA = high right atrium; RVA = right ventricular apex.

Atrial pacing at rates exceeding the tachycardia rate can demonstrate the ventricular origin of the wide-QRS tachycardia by producing fusion and capture beats and normalization of the H-V interval. The only VT that exhibits an H-V interval equal to or slightly exceeding the normal sinus H-V interval is bundle branch reentry, but His activation will be in the retrograde direction.

An EPS should be considered for the following circumstances:

(1) in patients who have symptomatic, recurrent, or drug-resistant supraventricular or ventricular tachyarrhythmias to help select optimal therapy; (2) in patients with tachyarrhythmias occurring too infrequently to permit adequate diagnostic or therapeutic assessment; (3) for differentiation of SVT and aberrant conduction from VT; (4) whenever nonpharmacologic therapy, such as the use of electrical devices, catheter ablation, or surgery, is contemplated; (5) in patients surviving an episode of cardiac arrest occurring more than 48 hours after acute myocardial infarction or without evidence of an acute Q wave myocardial infarction; and (6) for assessment of the risk for sustained VT in patients with a previous myocardial infarction, ejection fraction of 0.3 to 0.4, and nonsustained VT on an ECG. In general, EPS is not indicated in patients with long-QT syndrome and torsades de pointes.

The process of initiation and termination of SVT or VT with programmed electrical stimulation to establish precise diagnoses and help select sites for catheter ablation is the most common application of EPS in patients with tachycardia. The role of drug therapy in clinically significant arrhythmias continues to diminish; although EPS was once widely used to predict the efficacy of drug therapy in suppressing spontaneous tachycardia recurrences, the technique is now rarely used for this purpose. Noninvasive stimulation from an implanted pacemaker or defibrillator can be used to test the effects of drug therapy given in an attempt to decrease the frequency of arrhythmias, as well as to test the ICD's ability to detect and treat VT that has been slowed or otherwise altered by drug effect.

Unexplained Syncope

The three common arrhythmic causes of syncope are sinus node dysfunction, AV block, and tachyarrhythmias (see Chapter 40). Of the three, tachyarrhythmias are most reliably evaluated in the electrophysiology laboratory, followed by sinus node abnormalities and His-Purkinje block.

The cause of syncope remains uncertain in up to 50% of patients, depending in part on the extent of the evaluation. A careful, accurately performed history and physical examination begin the evaluation, followed by noninvasive tests, including a 12-lead ECG, and can lead to a diagnosis in 50% or more of patients. In a small percentage (<5%) of patients, an arrhythmia develops coincident with syncope or presyncope during 24- or 48-hour ECG monitoring, whereas a larger percentage (15%) have symptoms without an arrhythmia, thereby excluding an arrhythmic cause. Prolonged ECG monitoring with patient-activated transtelephonic event recorders that have memory loops may increase the yield. Tilt-table and stress testing can be useful for selected patients.

An EPS helps explain the cause of syncope or palpitations when it induces an arrhythmia that replicates the patient's symptoms or is associated with significant hypotension. Patients with a single episode of syncope and no evidence of structural heart disease, as well as those with a nondiagnostic EPS, have a low incidence of sudden death and an 80% remission rate over the ensuing 10 years. In those with recurrent syncope, the test is falsely negative in 20%, usually because of failure to find AV block or sinus node dysfunction.

FIGURE 34-11 Multiple abnormalities in a patient with prior myocardial infarction and syncope. Recordings are similar to previous figures. In the **left panel**, a sinus rhythm complex shows a right bundle branch block and left axis deviation, with a very prolonged H-V interval of 125 milliseconds (normal, 35 to 55 milliseconds); thus heart block could have caused syncope. However, in the **right panel**, ventricular stimulation with three extrastimuli (S_2 , S_3 , S_4) induces sustained VT, another potential cause of syncope (note the different time scales in the two panels).

On the other hand, in many patients with structural heart disease, several abnormalities may be present that could account for syncope and can be diagnosed at EPS. Deciding which among these abnormalities is responsible for syncope and therefore requires therapy, and of what type, can be difficult (Fig. 34-11). Mortality and the incidence of sudden cardiac death are determined mainly by the presence of underlying heart disease.

Syncope patients considered for an EPS are those whose spells remain undiagnosed despite general, neurologic, and noninvasive cardiac evaluation, particularly if the patient has structural heart disease.¹⁷ The diagnostic yield is approximately 70% in that group but only around 12% in patients without structural heart disease. Therapy for a putative cause found during EPS prevents recurrence of syncope in approximately 80% of patients. Among arrhythmic causes of syncope, intermittent conduction disturbances are the most difficult to diagnose. EPS is poor in establishing this diagnosis despite an array of provocative tests that can be used. When tachyarrhythmias have been thoroughly sought and excluded and clinical suspicion for intermittent heart block is high (e.g., bundle branch block or long H-V interval), empiric permanent pacing may be justified.

In patients with a nondiagnostic EPS, injection of adenosine triphosphate (different from plain adenosine) distinguishes patients who may benefit from permanent pacing (those with longer than a 10-second sinus pause or AV block) from those who do not. Some have suggested that this test be performed before EPS in some cases or after a negative EPS but before an implantable loop recorder is placed.¹⁸

Palpitations

An EPS is indicated in patients with palpitations who have had a pulse documented by medical personnel to be inappropriately rapid or slow without an electrocardiographic recording and in those suspected of having clinically significant palpitations without electrocardiographic documentation.

In patients with syncope or palpitations, the sensitivity of EPS may be low but can be increased at the expense of specificity. For example, more aggressive pacing techniques (e.g., use of three or four premature stimuli), administration of drugs (e.g., isoproterenol), or left ventricular pacing can increase the likelihood of induction of ventricular arrhythmias by precipitating *nonclinical* ventricular tachyarrhythmias, such as nonsustained polymorphic or monomorphic VT or VF. Similarly, aggressive techniques during atrial pacing can induce non-specific episodes of AF or atrial flutter. A diagnostic dilemma arises when the patient's clinical, symptom-producing arrhythmia is one of these nonspecific arrhythmias that can be produced in a normal patient who has no arrhythmia. In most patients, these arrhythmias are regarded as nonclinical (i.e., nonspecific responses to intense stimulation). In other patients, such as those with hypertrophic or dilated nonischemic cardiomyopathy, they may be clinically relevant arrhythmias. However, induction of sustained SVT (e.g., AV nodal reentry, AV reciprocating tachycardia) or monomorphic VT is almost

never an artifact of stimulation, no matter how intense. Initiation of these arrhythmias in patients who have not had known spontaneous episodes of these tachycardias is uncommon and provides important information; for example, the induced tachyarrhythmia may be clinically significant and responsible for the patient's symptoms. In addition, inducible SVT episodes can have important implications for patients with ICDs that may deliver inappropriate therapy for such arrhythmias. In general, other abnormalities, such as prolonged sinus pauses after overdrive atrial pacing or His-Purkinje AV block, are not induced in patients who do not or may not experience these abnormalities spontaneously. Provocation of these abnormalities has a high degree of specificity for clinical relevance.

Complications of Electrophysiologic Studies

The risks associated with undergoing only an EPS are small. Myocardial perforation with cardiac tamponade, pseudoaneurysms at arterial access sites, and provocation of nonclinical arrhythmias can occur, each with less than a 1 per 500 incidence. The addition of therapeutic maneuvers (e.g., ablation) to the procedure increases the incidence of complications. In a European survey of 4398 patients reported from 68 institutions, the rate of ablation procedure-related complications ranged from 3.2% to 8%. Five deaths occurred within the perioperative period of the ablation. In a Heart Rhythm Society (formerly North American Society of Pacing and Electrophysiology) survey of 164 hospitals reporting in 1998 on more than 3300 patients who had undergone radiofrequency ablation, complications developed in 1% to 3%, with procedure-related deaths occurring in approximately 0.2%. In a study of 1050 patients undergoing temperature-controlled ablation for supraventricular arrhythmias, 32 (3%) had a major complication. Predictors of major complications were ejection fractions lower than 0.35 and multiple ablation targets. The improvement in the complication rate probably reflects the learning curve for radiofrequency ablation. In many centers, diagnostic EPS and even ablation procedures are performed on an outpatient basis (i.e., same-day discharge). With the increasing use of extensive ablation in the left atrium to treat AF, an increase in systemic thromboembolic complications has been observed, as have pericardial effusion and tamponade, valve damage, and phrenic nerve injury (see Chapter 37).¹⁹

DIRECT CARDIAC MAPPING: RECORDING POTENTIALS DIRECTLY FROM THE HEART

Cardiac mapping is a method whereby potentials recorded directly from the heart are spatially depicted as a function of time in an integrated manner (Fig. 34-12). The location of recording electrodes (e.g., epicardial, intramural, or endocardial) and the recording mode used (unipolar versus bipolar), as well as the method of display (isopotential, isochronal, unipolar, or bipolar voltage maps), depend on the problem under consideration.

Direct cardiac mapping by catheter electrodes or, less commonly, at the time of cardiac surgery can be used to identify and localize the areas responsible for rhythm disturbances in patients with supraventricular and ventricular tachyarrhythmias for catheter or surgical ablation, isolation, or resection. Conditions amenable to this approach include accessory pathways associated with Wolff-Parkinson-White syndrome, the pathways in AV node reentry, AV node–His bundle ablation, sites of origin of focal atrial tachycardia and VTs, isolated pathways essential for the maintenance of reentrant atrial tachycardia or VTs, and various substrates responsible for episodes of AF (Videos 34-1 and 34-2) (see Chapter 38). Mapping can also be used to delineate the anatomic course of the His bundle to avoid injury during catheter ablation or open heart surgery for repair of congenital heart disease.

Early efforts at mapping involved moving an electrode from location to location, acquiring data from a single point at a time, and comparing the timing of local activation with some reference recording, as well as other mapped sites. Knowing when enough data points had been obtained to determine where ablation should be performed relied heavily on the memory of the operator. Specialized mapping systems have now been developed that use computers to log not only the activation times and electrogram amplitude (voltage) at various points in the heart but also the physical locations from which they were obtained.²⁰ The mapping information acquired in this way can be displayed on a screen to show relative activation times in a color-coded sequence. By use of such systems, dozens or even hundreds of sites can be sampled relatively quickly, thereby leading to a clear picture of cardiac activation and potential target sites for ablation (Figs. 34-13 and 34-14). These systems can also record the signal amplitude at each site sampled to allow differentiation of normal from scarred myocardium, which can help in planning ablation strategies (Fig. 34-15). Other mapping systems can acquire data from several thousand points simultaneously by using a multipolar electrode array. This is particularly useful for hemodynamically unstable tachycardias or those that terminate spontaneously within seconds, which precludes detailed point-to-point mapping.

FIGURE 34-12 Endocardial catheter recordings during VT in two patients. Dashed lines denote onset of the QRS complexes. **A**, A woman without structural heart disease had a sustained VT arising from the left ventricular outflow tract (LVOT). Note the unipolar (uni) electrogram with a sharp "QS" complex and onset (arrow) of the distal bipolar recording (LVOT_{dist}) preceding the right ventricular recording, as well as recordings from a multielectrode catheter in the great cardiac vein (GCV_{dist} and GCV_{prox}) on the epicardial surface opposite the endocardial recording. Ablation at this site (LVOT) terminated the VT. **B**, A patient with reentrant VT caused by a previous inferior wall infarction. The ablation catheter (Abl_{dist}) on the inferomedial wall shows a prolonged, fragmented electrogram indicative of slow conduction that spans the entire diastolic interval between QRS complexes. Ablation at this site eliminated the VT. Abl_{prox} = proximal ablation catheter electrodes.

**VIDEO 34-1**

Focal atrial tachycardia. The right atrium is shown in an antero-posterior view. The purple tube at top represents the superior vena cava, the circle in the middle right, the tricuspid annulus. Red indicates the head of the activation wavefront. Note the centrifugal propagation from a focus on the anterolateral right atrial wall. Ablation at the focus cured the patient from further tachycardia episodes.

VIDEO 34-2

Macroreentrant atrial tachycardia following atrial fibrillation ablation. The left atrium is shown from a right posterior oblique view; tubes emanating from the left atrium represent pulmonary veins. The red patch in the center is a diastolic corridor of reentry; the moving red border indicates the head of the advancing activation wavefront. Note the progression of the wavefront from the bottom of the diastolic corridor spreading to left and right, coming back around the top and coalescing at the top of the diastolic corridor to complete a reentrant cycle. Ablation across the diastolic corridor cured the patient from further tachycardia episodes.

FIGURE 34-13 Electroanatomic map of focal atrial tachycardia. Both the right (RA) and left atrium (LA) are shown in an almost head-on view. A color-coded time scale of activation is shown at the right; red indicates earliest activation, purple latest. A distance scale is shown below. This atrial tachycardia arose in the anteromedial portion of the left atrium (red spot), with all other areas activated centrifugally. Ablation at this site eliminated the tachycardia. LIPV = left inferior pulmonary vein (PV); LSPV = left superior PV; MV = mitral valve ring; RSPV = right superior PV; SVC = superior vena cava; TV = tricuspid valve ring; His bundle area indicated by orange circles.

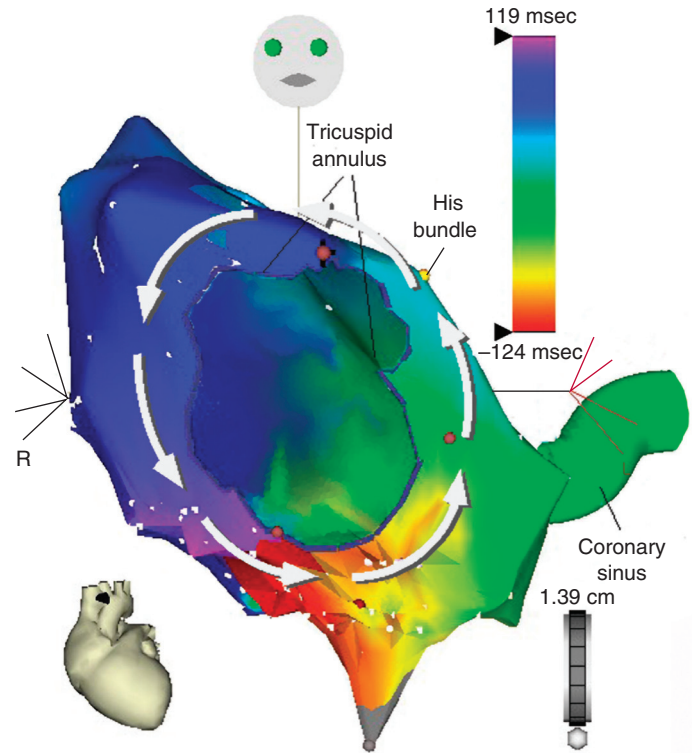

FIGURE 34-14 Electroanatomic map of reentrant atrial flutter. A left anterior oblique view of the right atrium is shown, along with depiction of the coronary sinus. See Figure 34-14 for other details. The electrical wave front propagates around the tricuspid annulus in a counterclockwise direction; in this complete circuit, early activation (in red) abuts late activation (purple) near the bottom of the tricuspid annulus. The cycle length of the tachycardia was 250 milliseconds, almost completely described by the points shown in the figure (from -124 to +119 milliseconds, a total of 243 milliseconds). A distance scale is shown below.

FIGURE 34-15 Electroanatomic left ventricular voltage maps during sinus rhythm. Right and left anterior oblique views are shown; the voltage scale at the right indicates normal areas (purple) versus scarred (gray) or very low-voltage areas (red, with gradation to higher voltages through green and blue). The patient had an old anteroapical myocardial infarction leading to reentrant VT that originated in the border between scar and more normal myocardium, LAO = left anterior oblique; RAO = right anterior oblique.

Pace mapping is a technique in which pacing is performed at putative sites from which arrhythmias arise (a focus) or exit (reentrant circuit). The greater the degree of “match” in QRS complexes (for VT) or intracardiac activation sequences (for atrial tachycardias), the more likely that the paced site may be an appropriate site for ablation. Software has been developed to calculate the fidelity of match of the paced complexes to the target arrhythmia; ideally, this should approach 100%. Other algorithms have been developed to analyze propagation patterns during complex arrhythmias such as AF by recording signals from multielectrode “basket” catheters in the atrium (Fig. 34-16); this has resolved many cases of an apparently chaotic rhythm to one in which erratic patterns of propagation emanate from a stable rapid source (either rotor or focus). Ablation at

these source sites can eliminate AF.²¹ Work is ongoing in this area. Finally, although computerized mapping systems acquire activation time and voltage at given sites in the heart, these features have been displayed separately. “Ripple mapping” is a new technique that integrates time and voltage information on the same display. Experience with this technique is limited, but the early results are promising.²²

Current mapping systems have the ability to both integrate previous imaging studies (computed tomography, magnetic resonance imaging) into the procedure for additional anatomic reference and derive anatomic information by moving a catheter throughout a cardiac chamber to develop a contour of its inner surface on which activation or voltage data can be plotted.

FIGURE 34-16 Basket catheter for mapping AF. Right and left anterior oblique fluoroscopic views are shown of an 8-spline, 8 electrode per spline (64 total electrodes) “basket” catheter in the left atrium; other catheters are right atrial (RA), coronary sinus (CS), and an ablation catheter (ABL) in the right inferior pulmonary vein.

GUIDELINES

Ambulatory Electrocardiographic and Electrophysiologic Testing

John M. Miller and Douglas P. Zipes

Guidelines for the appropriate use of ambulatory electrocardiography (ECG) were first published by the American College of Cardiology/American Heart Association (ACC/AHA) in 1989¹ and updated in 1999.² In conjunction with other professional societies, the ACC/AHA issued a statement of requirements for clinical competence in ambulatory ECG in 2001.³ Guidelines for performance of electrophysiologic testing were first published in 1985⁴ and updated in 1989 and 1995.⁵ A clinical competence statement was issued by the ACC/AHA for electrophysiologic studies and catheter ablation in 2000⁶; this was updated by a statement on training in electrophysiology, cardiac pacing, and arrhythmia management in 2006⁷ and again in 2008.⁸ The AHA and the North American Society of Pacing and Electrophysiology (NASPE, now the Heart Rhythm Society) made recommendations on safety-related topics, such as restrictions on driving,

for patients with arrhythmia in 1996⁹ and updated them in 2007¹⁰ (covered in the Guidelines in [Chapter 38](#)). Since then, efforts to update the guidelines have focused on appropriate indications for the use of pacemakers and implantable cardioverter-defibrillators (ICDs) because of rapid advances in knowledge about the ability of ICDs to improve the survival of patients with arrhythmia with or without electrophysiologic testing. These guidelines were issued in 2002¹¹ and updated in 2008 and 2013.¹² Guidelines on ICD use are further addressed in [Chapter 38](#).

The standard ACC/AHA classification system is used for the following indications:

- Class I: conditions for which there is evidence and/or general agreement that the test is useful and effective
- Class II: conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test
 - Class IIa: weight of evidence or opinion in favor of usefulness or efficacy
 - Class IIb: usefulness or efficacy less well established by evidence or opinion
- Class III: conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Three levels are used to rate the evidence on which recommendations have been based. Level A recommendations are derived from data from multiple randomized clinical trials, level B recommendations are derived from a single randomized trial or nonrandomized studies, and level C recommendations are based on the consensus opinion of experts.

AMBULATORY ELECTROCARDIOGRAPHY

The evolution of guidelines for the use of ambulatory ECG from 1989 to 1999 reflected important progress in several areas, including the following:

- Understanding of the limited usefulness of suppression of ventricular ectopy with drug therapy
- Solid-state digital technology, which facilitates transtelephonic transmission of electrocardiographic data
- Technical advances in long-term event recorders
- Improved signal quality and interpretation
- Improved computer arrhythmia interpretation

- Increasingly sophisticated monitoring capacity of pacemakers and ICDs

As a result of progress in these areas and increased knowledge about arrhythmias, ambulatory ECG is now considered to be of uncertain appropriateness for many indications for which it was once an accepted strategy.

Diagnosis

In assessing symptoms that may be caused by arrhythmias, ambulatory ECG (Holter) monitoring is clearly established for the evaluation of syncope (**Table 34G-1**; see **Chapter 40**). A 2006 AHA/ACC Foundation scientific statement on the evaluation of syncope stipulates that the type and duration of ambulatory ECG monitoring are dictated by the frequency of symptoms.¹³ Holter monitors (24 to 48 hours) are appropriate for episodes that occur at least daily and event recorders (30 to 60 days) for episodes that occur at least monthly. Implantable loop recorders inserted subcutaneously can record bipolar ECG signals for up to 14 months. In patients with unexplained syncope, use of an implantable loop recorder for 1 year is more likely to

TABLE 34G-1 ACC/AHA Guidelines on Ambulatory Electrocardiography for Assessment of Symptoms and Arrhythmias

INDICATION	CLASS I (INDICATED)	CLASS IIA (GOOD SUPPORTIVE EVIDENCE)	CLASS IIB (WEAK SUPPORTIVE EVIDENCE)	CLASS III (NOT INDICATED)
Assessment of symptoms possibly related to rhythm disturbances	Patients with unexplained syncope, near-syncope, or episodic dizziness in whom the cause is not obvious Patients with unexplained recurrent palpitation		Patients with episodic shortness of breath, chest pain, or fatigue that is not otherwise explained Patients with neurologic events when transient atrial fibrillation or flutter is suspected Patients with symptoms such as syncope, near-syncope, episodic dizziness, or palpitation in whom a probable cause other than an arrhythmia has been identified but in whom symptoms persist despite treatment of this other cause	Patients with symptoms such as syncope, near-syncope, episodic dizziness, or palpitation in whom other causes have been identified by history, physical examination, or laboratory tests Patients with cerebrovascular accidents but without other evidence of arrhythmia
Arrhythmia detection to assess risk for future cardiac events in patients without symptoms from arrhythmia			Post-MI patients with LV dysfunction (ejection fraction <40%) Patients with CHF Patients with idiopathic hypertrophic cardiomyopathy	Patients who have sustained myocardial contusion Systemic hypertensive patients with LV hypertrophy Post-MI patients with normal LV function Preoperative arrhythmia evaluation of patients for noncardiac surgery Patients with sleep apnea Patients with valvular heart disease
Measurement of heart rate variability to assess risk for future cardiac events in patients without symptoms from arrhythmia			Post-MI patients with LV dysfunction Patients with CHF Patients with idiopathic hypertrophic cardiomyopathy	Post-MI patients with normal LV function Diabetic subjects to evaluate for diabetic neuropathy Patients with rhythm disturbances that preclude HRV analysis (e.g., atrial fibrillation)
Assessment of antiarrhythmic therapy	To assess antiarrhythmic drug response in individuals in whom the baseline frequency of arrhythmia has been characterized as reproducible and of sufficient frequency to permit analysis	To detect proarrhythmic responses to antiarrhythmic therapy in patients at high risk	To assess rate control during atrial fibrillation To document recurrent or asymptomatic nonsustained arrhythmias during therapy in the outpatient setting	

CHF = congestive heart failure; HRV = heart rhythm variability; LV = left ventricular; MI = myocardial infarction.

**TABLE 34G-2 ACC/AHA Guidelines on Ambulatory Electrocardiography for Assessment of Pacemaker and Implantable Cardioverter-Defibrillator Function**

CLASS	INDICATION
Class I (indicated)	Evaluation of frequent symptoms of palpitations, syncope, or near-syncope to assess device function, to exclude myopotential inhibition and pacemaker-mediated tachycardia, and to assist in the programming of enhanced features, such as rate responsivity and automatic mode switching Evaluation of suspected component failure or malfunction when device interrogation is not definitive in establishing a diagnosis To assess response to adjunctive pharmacologic therapy in patients receiving frequent ICD therapy
Class IIa (good supportive evidence)	
Class IIb (weak supportive evidence)	Evaluation of immediate postoperative pacemaker function after pacemaker or ICD implantation as an alternative or adjunct to continuous telemetric monitoring Evaluation of the rate of supraventricular arrhythmias in patients with implanted defibrillators
Class III (not indicated)	Assessment of ICD or pacemaker malfunction when device interrogation, electrocardiogram, or other available data (e.g., chest radiograph) are sufficient to establish an underlying cause or diagnosis Routine follow-up in asymptomatic patients

identify the mechanism of syncope than is a conventional approach that uses Holter or event monitors and electrophysiologic testing and is cost-effective.

Ambulatory ECG is also supported for the evaluation of recurrent palpitations, particularly if the frequency of these symptoms makes it reasonably likely that they can be correlated with the tracings obtained during a 24-hour monitoring period. The guidelines note that data on the use of ambulatory ECG for near-syncope or dizziness are insufficient to describe the diagnostic performance of this technology for patients with such symptoms.

The ACC/AHA guidelines explicitly discourage ambulatory ECG for patients with syncope or palpitations if other causes have been identified during the clinical evaluation and for patients with cerebrovascular accidents and no other evidence of arrhythmia. The guidelines seek to reduce performance of ambulatory ECG “for completeness” in such cases. Little support is provided for use of ambulatory ECG in cases in which the cause of the patient’s symptoms is unclear but in which the likelihood of detecting an unsuspected arrhythmia is low (class IIb indications).

Assessment of Risk

The ACC/AHA guidelines discouraged the use of ambulatory ECG for either arrhythmia detection or analysis of heart rhythm variability for the purpose of risk assessment in patients without symptoms of arrhythmia, even if they had cardiovascular conditions such as myocardial contusions, left ventricular hypertrophy, or valvular heart disease (see [Table 34G-1](#)). Routine use for patients in whom arrhythmia is a common cause of death (left ventricular dysfunction, hypertrophic cardiomyopathy) was considered a class IIb indication. These recommendations preceded data demonstrating the beneficial impact of ICDs for patients with left ventricular dysfunction after acute myocardial infarction even without symptoms of arrhythmia. These more recent findings are leading to an expanded role for ambulatory ECG in determining which asymptomatic patients most need these expensive devices.

Efficacy of Antiarrhythmic Therapy

In the absence of data demonstrating that oral antiarrhythmic therapy can improve survival through control of ventricular arrhythmias, ambulatory ECG has a diminished role as a test for evaluation of the efficacy of treatment (see [Table 34G-1](#)). Oral antiarrhythmic agents are important for control of supraventricular arrhythmias, but most patients with such arrhythmias do not have episodes every day. Event recorders can be useful for documenting the relationship between symptoms and recurrent arrhythmia and the interval between episodes, which can help guide therapy.

The guidelines provide some support of the use of ambulatory ECG for detection of proarrhythmia during initiation of drug therapy, but

TABLE 34G-3 ACC/AHA Guidelines on Monitoring for Ischemia

CLASS	INDICATION
Class I (indicated)	
Class IIa (good supportive evidence)	Patients with suspected variant angina
Class IIb (weak supportive evidence)	Evaluation of patients with chest pain who cannot exercise Preoperative evaluation for vascular surgery in patients who cannot exercise Patients with known coronary artery disease and atypical chest pain syndrome
Class III (not indicated)	Initial evaluation of patients with chest pain who are able to exercise Routine screening of asymptomatic subjects

patients at high risk for such complications tend to have these medications initiated as inpatients.

Assessment of Pacemaker and Implantable Cardioverter-Defibrillator Function

Ambulatory ECG was considered to be appropriate for evaluation of the function of pacemakers and ICDs (see [Chapter 36](#)), but the role of ambulatory ECG is being reduced by increasing the diagnostic and monitoring functions being built into these devices, especially with the use of remote monitoring. Ambulatory ECG can provide useful information by correlating symptoms with device activity and by detecting abnormalities in sensing and capture during chronic follow-up ([Table 34G-2](#)). However, the ACC/AHA guidelines emphasize that ambulatory ECG should not be used when data available from device interrogation are sufficient to guide clinical management.

Monitoring for Myocardial Ischemia

The 1999 ACC/AHA guidelines do not provide strong support of any indications for routine clinical use of ambulatory ECG monitoring for myocardial ischemia ([Table 34G-3](#)). The only indication for which the task force thought that there was good supportive evidence was suspected variant angina. This technology was not considered a first-choice alternative to exercise testing for patients who are unable to exercise.

Clinical Competence

The ACC/AHA statement on clinical competence recommended that trainees interpret at least 150 ambulatory electrocardiograms under

supervision to acquire minimal competence in this technology.³ A minimum of 25 test interpretations per year was recommended to maintain competence.

ELECTROPHYSIOLOGIC PROCEDURES FOR DIAGNOSIS

The ACC/AHA guidelines for the use of intracardiac electrophysiologic procedures from 1985⁴ and 1995⁵ reflect the emerging role of catheter ablation as a therapeutic strategy but do not fully reflect the reduced importance of antiarrhythmic medications and the growing role of ICDs that have occurred. Nevertheless, most of the basic themes of these guidelines remain valid. An updated clinical competence statement for performing these procedures was issued in 2006.¹⁴

Evaluation of Sinus Node Function

Clinical evaluation of sinus node dysfunction is often difficult because of the episodic nature of symptomatic abnormalities and the wide

variability in sinus node function in asymptomatic individuals. Invasive tests of sinus function can test the ability of the sinus node to recover from overdrive suppression and assess sinoatrial conduction by introducing atrial extrastimuli or by atrial pacing.

The ACC/AHA guidelines consider electrophysiologic studies of sinus node function most appropriate for patients in whom dysfunction is suspected but not proved after a noninvasive evaluation (Table 34G-4). In contrast, the guidelines consider such studies inappropriate when a documented bradyarrhythmia has been found to be correlated with the patient's symptoms and management is unlikely to be influenced by an electrophysiologic study. Studies are also considered inappropriate in asymptomatic patients and those who have sinus pauses only during sleep. When bradyarrhythmias were recognized as the cause of the patient's symptoms, electrophysiologic studies were considered to have possible but uncertain appropriateness (class II) if such data might refine treatment choices.

Acquired Atrioventricular Block

The ACC/AHA guidelines emphasize that electrophysiologic studies are inappropriate (class III) when ECG findings correlate with

TABLE 34G-4 ACC/AHA Guidelines on Clinical Intracardiac Electrophysiologic Studies for Evaluation of Specific Electrocardiographic Abnormalities

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Evaluation of sinus node function	Symptomatic patients in whom sinus node dysfunction is suspected as the cause of symptoms but a causal relationship between an arrhythmia and the symptoms has not been established after appropriate evaluation	Patients with documented sinus node dysfunction in whom evaluation of AV or ventriculoatrial conduction or susceptibility to arrhythmias may aid in selection of the most appropriate pacing modality Patients with electrocardiographically documented sinus bradyarrhythmias to determine whether abnormalities are caused by intrinsic disease, autonomic nervous system dysfunction, or effects of drugs to help select therapeutic options Symptomatic patients with known sinus bradyarrhythmias to evaluate potential for other arrhythmias as the cause of symptoms	Symptomatic patients in whom an association between symptoms and a documented bradyarrhythmia has been established and the choice of therapy would not be affected by the results of an electrophysiologic study Asymptomatic patients with sinus bradyarrhythmias or sinus pauses observed only during sleep, including sleep apnea
Acquired AV block	Symptomatic patients in whom His-Purkinje block, suspected as a cause of symptoms, has not been established Patients with second- or third-degree AV block treated with a pacemaker who remain symptomatic and in whom another arrhythmia is suspected as a cause of the symptoms	Patients with second- or third-degree AV block in whom knowledge of the site of block or its mechanism or response to pharmacologic or other temporary intervention may help in directing therapy or assessing prognosis Patients with premature, concealed junctional depolarizations suspected as the cause of a second- or third-degree AV block pattern (e.g., pseudo-AV block)	Symptomatic patients in whom the symptoms and presence of AV block are correlated by ECG findings Asymptomatic patients with transient AV block associated with sinus slowing (e.g., nocturnal type I second-degree AV block)
Chronic intraventricular conduction delay	Symptomatic patients in whom the cause of symptoms is not known	Asymptomatic patients with bundle branch block in whom pharmacologic therapy that could increase conduction delay or produce heart block is contemplated	Asymptomatic patients with intraventricular conduction delay Symptomatic patients whose symptoms can be correlated with or excluded by ECG events
Narrow-QRS tachycardia (QRS complex <0.12 sec)	Patients with frequent or poorly tolerated episodes of tachycardia who do not adequately respond to drug therapy and for whom information about the site of origin, mechanism, and electrophysiologic properties of pathways of the tachycardia is essential for choosing appropriate therapy (e.g., drugs, catheter ablation, pacing, or surgery) Patients who prefer ablative therapy to pharmacologic treatment	Patients with frequent episodes of tachycardia requiring drug treatment for whom there is concern about proarrhythmia or effects of the antiarrhythmic drug on the sinus node or AV conduction	Patients with tachycardias easily controlled by vagal maneuvers and/or well-tolerated drug therapy who are not candidates for nonpharmacologic therapy

Continued

**TABLE 34G-4 ACC/AHA Guidelines on Clinical Intracardiac Electrophysiologic Studies for Evaluation of Specific Electrocardiographic Abnormalities—cont'd**

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Wide-complex tachycardias	Patients with wide-QRS complex tachycardia in whom the correct diagnosis is unclear after analysis of available ECG tracings and for whom knowledge of the correct diagnosis is necessary for care	None	Patients with VT or supraventricular tachycardia with aberrant conduction or preexcitation syndromes diagnosed with certainty by ECG criteria and for whom invasive electrophysiologic data would not influence therapy; however, data obtained at baseline electrophysiologic study in these patients might be appropriate as a guide for subsequent therapy
Prolonged-QT interval syndrome	None	Identification of proarrhythmic effect of a drug in patients experiencing sustained VT or cardiac arrest while receiving the drug Patients who have equivocal abnormalities in QT interval duration or TU wave configuration, along with syncope or symptomatic arrhythmias, in whom the effects of catecholamine may unmask a distinct QT abnormality	Patients with clinically manifest congenital QT prolongation, with or without symptomatic arrhythmias Patients with acquired prolonged-QT syndrome with symptoms closely related to an identifiable cause or mechanism
Wolff-Parkinson-White syndrome	Patients being evaluated for catheter ablation or surgical ablation of an accessory pathway Patients with ventricular preexcitation who have survived cardiac arrest or who have unexplained syncope Symptomatic patients in whom determination of the mechanism of arrhythmia or knowledge of the electrophysiologic properties of the accessory pathway and normal conduction system would help in determining appropriate therapy	Asymptomatic patients with a family history of sudden cardiac death or with ventricular preexcitation but no spontaneous arrhythmia who engage in high-risk occupations or activities and in whom knowledge of the electrophysiologic properties of the accessory pathway or inducible tachycardia may help determine recommendations for further activities or therapy Patients with ventricular preexcitation who are undergoing cardiac surgery for other reasons	Asymptomatic patients with ventricular preexcitation, except those in class II
Ventricular premature complexes, couplets, and nonsustained VT	None	Patients with other risk factors for future arrhythmic events, such as a low ejection fraction, positive signal-averaged electrocardiogram, and nonsustained VT on ambulatory ECG recordings in whom electrophysiologic studies will be used for further risk assessment and for guiding therapy in patients with inducible VT Patients with highly symptomatic, uniform-morphology premature ventricular complexes, couplets, and nonsustained VT who are considered potential candidates for catheter ablation	Asymptomatic or mildly symptomatic patients with premature ventricular complexes, couplets, and nonsustained VT without other risk factors for sustained arrhythmias

VT = ventricular tachycardia.

symptoms and the findings from electrophysiologic studies are unlikely to alter management (e.g., documentation of His bundle conduction rarely improves the management of a patient whose other clinical data indicate that placement of a permanent pacemaker is warranted because of symptomatic advanced atrioventricular [AV] block). Similarly, electrophysiologic studies are not appropriate for asymptomatic patients with mild degrees of AV block who are not likely to warrant pacemaker implantation. According to these guidelines, electrophysiologic studies of AV conduction should be performed when a relationship between symptoms and AV block is a reasonable possibility but has not been proved.

Chronic Intraventricular Delay

According to the ACC/AHA guidelines, the main role of electrophysiologic testing in patients with prolonged H-V intervals is not to predict

future complications but to determine whether the symptoms of arrhythmia are caused by conduction delay or block versus some other arrhythmia. The only class I (clearly appropriate) indication for electrophysiologic testing is symptomatic patients for whom the cause of symptoms is not known. The guidelines specifically discourage such testing of asymptomatic patients and provide only equivocal support for asymptomatic patients with bundle branch block in whom treatment with drugs that might increase conduction delay is being considered.

Narrow- and Wide-QRS Complex Tachycardia

The ACC/AHA guidelines define different roles for electrophysiologic testing in patients with narrow- and wide-complex tachycardias. In narrow-QRS tachycardia, the site of abnormal impulse formation or

the reentry circuit can often be determined from information on the 12-lead electrocardiogram. Thus electrophysiologic testing was considered more appropriate as a guide to therapy in this setting than as a tool for diagnosis. Class I indications for electrophysiologic testing include patients with recurrent tachycardia for whom data from testing may help clinicians choose among drug therapy, catheter ablation, pacing, and surgery. However, testing is not considered useful for patients whose tachycardias are controlled by vagal maneuvers or medications and who are not candidates for nonpharmacologic therapy.

In wide-complex tachycardias, correct diagnosis is occasionally not possible from ECG tracings alone. However, electrophysiologic testing permits accurate diagnosis in virtually all patients. Because knowledge of the mechanism of the arrhythmia is essential for selection of optimal therapy, electrophysiologic testing was considered appropriate (class I) for the diagnosis of wide-complex tachycardias in these guidelines. However, when the diagnosis is clear from other data and electrophysiologic testing is not likely to influence therapy, the guidelines consider it inappropriate.

Prolonged QT Intervals

The ACC/AHA guidelines do not consider routine use of electrophysiologic testing appropriate for any indications in patients with prolonged QT intervals. Whether catecholamine infusion during testing is useful for revealing patients who are at high risk for complications or whether electrophysiologic testing can be used to evaluate proarrhythmic effects in this population is considered uncertain.

Wolff-Parkinson-White Syndrome

Electrophysiologic testing is useful for patients with this syndrome for both diagnosis and planning of therapy. The ACC/AHA guidelines consider electrophysiologic testing appropriate for patients who are candidates for catheter or surgical ablation, for those who have had cardiac arrests or unexplained syncope, or for patients whose management might be altered by knowledge of the electrophysiologic properties of the accessory pathway and normal conduction system. For asymptomatic patients, however, electrophysiologic studies are deemed inappropriate except in special situations, such as patients with high-risk occupations or those with a family history of sudden cardiac death. More recently recognized entities, such as Brugada

syndrome, catecholaminergic tachycardia, and right ventricular cardiomyopathy, were not considered.

Nonsustained Ventricular Tachycardia

For patients with ventricular premature complexes, couplets, and nonsustained ventricular tachycardia, the usefulness of electrophysiologic testing is compromised by the lack of therapeutic strategies that have been shown to improve outcomes. There are no clearly appropriate indications for electrophysiologic studies in these patients, and the guidelines discourage testing in patients without other risk factors for sustained arrhythmias. Research published since these guidelines suggests that exceptions would include patients who fit the MADIT (Multicenter Automatic Defibrillator Implantation Trial) or MUSTT (Multicenter Unsustained Tachycardia Trial) criteria. For certain patients with other data suggesting an adverse prognosis, electrophysiologic testing is thought to have possible but unproven appropriateness (class II).

Unexplained Syncope

In patients with unexplained syncope and structural heart disease (see Chapter 40), recent ACC/AHA guidelines on the evaluation of syncope¹⁰ recommend a low threshold for the use of electrophysiologic testing (Table 34G-5). In patients without structural heart disease, the yield of electrophysiologic testing is low. Thus the guidelines recommend a higher threshold for use of electrophysiologic studies in such patients and suggest that head-up tilt testing may be a more useful test. However, given the low risk associated with electrophysiologic testing and the high risk for potentially harmful recurrent syncope, electrophysiologic testing may be beneficial for patients with a malignant episode of syncope.¹³

Survivors of Cardiac Arrest

The ACC/AHA guidelines consider electrophysiologic testing appropriate for patients who are survivors of cardiac arrest (see Chapter 39) other than in the earliest phase of acute myocardial infarction (see Table 34G-5). Since publication of these guidelines, acceptance of the usefulness of ICDs has become more widespread, and many of these patients receive such a device without electrophysiologic testing or undergo limited electrophysiologic testing at device

TABLE 34G-5 ACC/AHA Guidelines on Clinical Intracardiac Electrophysiologic Studies for Evaluation of Clinical Syndromes

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Unexplained syncope	Patients with suspected structural heart disease and syncope that remain unexplained after appropriate evaluation	Patients with recurrent unexplained syncope but without structural heart disease and a negative head-up tilt test result	Patients with a known cause of syncope for whom treatment will not be guided by electrophysiologic testing
Survivors of cardiac arrest	Patients surviving cardiac arrest without evidence of acute Q wave MI Patients surviving cardiac arrest occurring more than 48 hr after the acute phase of MI in the absence of recurrent ischemic events	Patients surviving cardiac arrest caused by bradyarrhythmia Patients surviving cardiac arrest thought to be associated with a congenital repolarization abnormality (long-QT syndrome) in whom the results of noninvasive diagnostic testing are equivocal	Patients surviving a cardiac arrest that occurred during the acute phase (<48 hr) of MI Patients with cardiac arrest resulting from clearly definable specific causes, such as reversible ischemia, severe valvular aortic stenosis, or noninvasively defined congenital or acquired long-QT syndrome
Unexplained palpitations	Patients with palpitations who have their pulse rate documented by medical personnel as inappropriately rapid and in whom ECG recordings fail to document the cause of the palpitations Patients with palpitations preceding a syncopal episode	Patients with clinically significant palpitations, suspected to be of cardiac origin in whom the symptoms are sporadic and cannot be documented; studies performed to determine mechanisms of arrhythmias, direct or provide therapy, or assess prognosis	Patients with palpitations documented to be due to extracardiac causes (e.g., hyperthyroidism)

MI = myocardial infarction.

implantation. The guidelines consider electrophysiologic studies inappropriate when cardiac arrest has occurred within the first 48 hours of myocardial infarction or when the cardiac arrest results from clearly definable specific causes.

Unexplained Palpitations

The procedure of choice to determine the cause of palpitations is ambulatory ECG according to the ACC/AHA guidelines. The guidelines suggest that electrophysiologic testing should be reserved for patients with palpitations that are associated with syncope or for those in whom electrocardiograms have failed to capture a cause of the palpitations but who have been noted to have a rapid pulse rate by medical personnel (see Table 34G-5). Electrophysiologic testing is considered to be of equivocal value in patients with symptoms so sporadic that they cannot be documented while ambulatory ECG is performed.

ELECTROPHYSIOLOGIC STUDIES FOR THERAPEUTIC INTERVENTION

The 1995 ACC/AHA guidelines on the appropriateness of electrophysiologic studies for guidance of drug therapy and implantable electrical devices do not reflect the decline in the role of oral antiarrhythmic therapy and the rise in the use of ICDs for the treatment of patients who have experienced cardiac arrest (Table 34G-6). However, the guideline recommendations for the role of catheter ablation remain valid. Characteristics that are common among appropriate indications include supraventricular arrhythmias, including atrial fibrillation, that are symptomatic; that cannot be controlled with medications because of limited effectiveness, side effects, or inconvenience; or that have caused sudden cardiac death.¹⁵ Catheter ablation is also useful for the same reasons in some patients with ventricular tachycardia when it occurs in the absence of structural heart disease, and

TABLE 34G-6 ACC/AHA Guidelines on Clinical Intracardiac Electrophysiologic Studies for Therapeutic Intervention

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Guidance of drug therapy	Patients with sustained VT or cardiac arrest, especially those with prior MI Patients with AVNRT, AV reentrant tachycardia using an accessory pathway, or atrial fibrillation associated with an accessory pathway for whom chronic drug therapy is planned	Patients with sinus node reentrant tachycardia, atrial tachycardia, atrial fibrillation, or atrial flutter without ventricular preexcitation syndrome for whom chronic drug therapy is planned Patients with arrhythmias not inducible during controlled electrophysiologic study for whom drug therapy is planned	Patients with isolated atrial or ventricular premature complexes Patients with ventricular fibrillation with a clearly identified reversible cause
Patients who are candidates for or who have implantable electrical devices	Patients with tachyarrhythmias before and during implantation and final (predischARGE) programming of an electrical device to confirm its ability to perform as anticipated Patients with an implanted electrical antitachyarrhythmia device in whom changes in status or therapy may have influenced the continued safety and efficacy of the device Patients who have a pacemaker to treat a bradyarrhythmia and receive a cardioverter-defibrillator to test for device interactions	Patients with previously documented indications for pacemaker implantation to test for the most appropriate long-term pacing mode and sites to optimize symptomatic improvement and hemodynamics	Patients who are not candidates for device therapy
Indications for catheter ablation procedures	Patients with symptomatic atrial tachyarrhythmias who have inadequately controlled ventricular rates unless primary ablation of the atrial tachyarrhythmia is possible Patients with symptomatic atrial tachyarrhythmias such as those above but in whom drugs are not tolerated or the patient does not wish to take them, even though the ventricular rate can be controlled Patients with symptomatic nonparoxysmal junctional tachycardia that is drug resistant or the patient is drug intolerant or does not wish to take it Patients resuscitated from sudden cardiac death caused by atrial flutter or atrial fibrillation with a rapid ventricular response in the absence of an accessory pathway	Patients with a dual-chamber pacemaker and pacemaker-mediated tachycardia that cannot be treated effectively by drugs or by reprogramming the pacemaker	Patients with atrial tachyarrhythmias responsive to drug therapy acceptable to the patient
Radiofrequency catheter ablation for AVNRT	Patients with symptomatic sustained AVNRT that is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy	Patients with sustained AVNRT identified during electrophysiologic study or catheter ablation of another arrhythmia Finding of dual-AV nodal pathway physiology and atrial echoes but without AVNRT during electrophysiologic study in patients clinically suspected of having AVNRT	Patients with AVNRT responsive to drug therapy that is well tolerated and preferred by the patient over ablation Finding of dual-AV nodal pathway physiology (with or without echo complexes) during electrophysiologic study in patients in whom AVNRT is not suspected clinically

TABLE 34G-6 ACC/AHA Guidelines on Clinical Intracardiac Electrophysiologic Studies for Therapeutic Intervention—cont'd

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Ablation of atrial tachycardia, flutter, and fibrillation: atrium/atrial sites	Patients with atrial tachycardia that is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial flutter that is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy	Atrial flutter or atrial tachycardia associated with paroxysmal atrial fibrillation when the tachycardia is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial fibrillation and evidence of a localized site of origin when the tachycardia is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy	Patients with atrial arrhythmia responsive to drug therapy that is well tolerated and preferred by the patient over ablation Patients with multifocal atrial tachycardia
Ablation of atrial tachycardia, flutter, and fibrillation: accessory pathways	Patients with symptomatic AV reentrant tachycardia that is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial fibrillation (or other atria tachyarrhythmia) and a rapid ventricular response through the accessory pathway when the tachycardia is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy	Patients with AV reentrant tachycardia or atrial fibrillation with rapid ventricular rates identified during electrophysiologic study for another arrhythmia Asymptomatic patients with ventricular preexcitation whose livelihood or profession, important activities, insurability, or mental well-being or the public safety would be affected by spontaneous tachyarrhythmias or the presence of the ECG abnormality Patients with atrial fibrillation and a controlled ventricular response through the accessory pathway Patients with a family history of sudden cardiac death	Patients who have accessory pathway–related arrhythmias responsive to drug therapy that is well tolerated and preferred by the patient over ablation
Ablation of VT	Patients with symptomatic sustained monomorphic VT when the tachycardia is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy Patients with bundle branch reentrant VT Patients with sustained monomorphic VT and an ICD who are receiving multiple shocks not manageable by reprogramming or concomitant drug therapy	Nonsustained VT that is symptomatic when the tachycardia is drug resistant or the patient is drug intolerant or does not desire long-term drug therapy	Patients with VT responsive to drug, ICD, or surgical therapy that is well tolerated and preferred by the patient over ablation Asymptomatic and clinically benign nonsustained VT

AVNRT = AV nodal reentrant tachycardia; MI = myocardial infarction; VT = ventricular tachycardia.

ablation is often useful as an adjunct to ICD implantation to limit episodes of ventricular tachycardia requiring ICD treatment.¹⁶ Left ventricular dysfunction develops in some patients from frequent premature ventricular complexes, with reversal occurring after ablation of the premature ventricular complex.

Clinical Competence

The ACC/AHA statement on clinical competence⁸ describes three levels of training: level 1 for every cardiology trainee, level 2 for those wishing to acquire advanced training in the management of arrhythmia, and level 3 for those intending to specialize in invasive diagnostic and therapeutic cardiac electrophysiology. The level 3 guidelines recommend a minimum of 1 year of specialized training in electrophysiologic studies, during which the physician should be the primary operator and analyze 100 to 150 initial diagnostic studies, at least 50 of which should involve patients with supraventricular arrhythmias. Because antiarrhythmic devices constitute a major part of current electrophysiology practice, the guidelines suggest that a trainee should be the primary operator during at least 25 electrophysiologic evaluations of implantable antiarrhythmic devices. For maintenance of competence, a minimum of 100 diagnostic electrophysiologic studies per year is recommended. The statement also recommends that specialists in electrophysiology attend at least 30 hours of formal continuing medical education every 2 years to remain abreast of changes in knowledge and technology.

For physicians who perform catheter ablation, the NASPE Ad Hoc Committee on Catheter Ablation (now the Heart Rhythm Society) has recommended that training should include at least 75 catheter ablations, at least 10 of which are accessory pathway ablations and 30 to 50 are mentored ablations.⁸ The ACC/AHA statement recommends that physicians who perform ablations carry out at least 20 to 50 ablations per year.

Individuals receiving training in pacemaker implantation must participate as the primary operator (under direct supervision) in at least 50 primary implantations of transvenous pacemakers and 20 pacemaker system revisions or replacements. At least half of the implantations should involve dual-chamber pacemakers. The trainee must also participate in the follow-up of at least 100 pacemaker patient visits and acquire proficiency in advanced pacemaker electrocardiography, interrogation, and programming of complex pacemakers.⁸

REFERENCES, 720

Treatment of patients with tachyarrhythmias has evolved dramatically over the last 40 years. Antiarrhythmic drugs were the mainstay of therapy until the late 1960s, when surgical therapy to cure, not just suppress tachyarrhythmias was developed. This mode was replaced by catheter ablation for better control or even cure of tachyarrhythmias in the 1980s. Catheter ablation has largely replaced surgical and drug therapy for patients who need treatment of supraventricular tachycardia (SVT) and ventricular tachycardia (VT) in the absence of structural heart disease. The implantable cardioverter-defibrillator (ICD) was introduced in the early 1980s and has become standard therapy for patients with serious ventricular arrhythmias in the presence of structural heart disease. Some patients require a combination of these forms of treatment (hybrid therapy, such as an ICD and antiarrhythmic drugs or surgery and an ICD); drug therapy can also affect ICD function, either positively or negatively. Drug therapy for arrhythmias, at one time the only option, has largely been replaced as the mainstay of therapy by ablation or implanted devices. However, in most patients, tachyarrhythmias are initially treated with antiarrhythmic drugs, and thus they continue to have a significant role.

PHARMACOLOGIC THERAPY

The principles of clinical pharmacokinetics and pharmacodynamics are discussed in [Chapter 9](#).

General Considerations Regarding Antiarrhythmic Drugs

Most of the antiarrhythmic drugs available ([Table 35-1](#)) can be classified according to whether they exert blocking actions predominantly on sodium, potassium, or calcium channels and whether they block receptors. The commonly used classification, that of Vaughan Williams, is limited because it is based on the electrophysiologic effects exerted by an arbitrary concentration of the drug, generally on a laboratory preparation of normal cardiac tissue. In reality, the actions of these drugs are complex and depend on tissue type, degree of acute or chronic damage, heart rate, membrane potential, ionic composition of the extracellular milieu, autonomic influence, genetics ([see Chapter 32](#)), age ([see Chapter 76](#)), and other factors ([see Table 35-1](#)). Many drugs exert more than one type of electrophysiologic effect or operate indirectly, such as by altering hemodynamics, myocardial metabolism, or autonomic neural transmission. Some drugs have active metabolites that exert effects different from those of the parent compound. Not all drugs in the same class have identical effects (e.g., amiodarone, sotalol, and ibutilide). Whereas all class III agents are dramatically different, some drugs in different classes have overlapping actions (e.g., class IA and class IC drugs). Thus, *in vitro* studies on healthy myocardium usually establish the properties of antiarrhythmic agents rather than their actual antiarrhythmic properties *in vivo*.

Despite its limitations, the Vaughan Williams classification is widely known and provides a useful communication shorthand, but the reader is cautioned that drug actions are more complex than those depicted by the classification. A more realistic view of antiarrhythmic agents is provided by the Sicilian gambit. This approach to drug classification is an attempt to identify the mechanisms of a particular arrhythmia, to determine the vulnerable parameter of the arrhythmia most susceptible to modification, to define the target most likely to affect the vulnerable parameter, and then to select a drug that will modify the target.¹ This concept provides a framework in which to consider antiarrhythmic drugs ([Table 35-2](#); also see [Table 35-1](#)).

Drug Classification

According to the Vaughan Williams classification, class I drugs predominantly block the fast sodium channel; they can also block potassium channels. They, in turn, are divided into three subgroups, classes IA, IB, and IC ([Table 35-3](#)).

Class IA

This class includes drugs that reduce \dot{V}_{max} (rate of rise in action potential upstroke [phase 0]) and prolong the action potential duration (APD; [see Chapter 33](#))—quinidine, procainamide, and disopyramide. The kinetics of onset and offset of class IA drugs in blocking the Na^+ channel is of intermediate rapidity (less than 5 seconds) when compared with class IB and class IC agents.

Class IB

This class of drugs does not reduce \dot{V}_{max} and shortens the APD—mexiletine, phenytoin, and lidocaine. The kinetics of onset and offset of these drugs in blocking the sodium channel is rapid (less than 500 milliseconds).

Class IC

This class of drugs, including flecainide and propafenone, can reduce \dot{V}_{max} , primarily slow conduction velocity, and prolong refractoriness minimally. These drugs have slow onset and offset kinetics (10 to 20 seconds).

Class II

These drugs block beta-adrenergic receptors and include propranolol, metoprolol, nadolol, carvedilol, nebivolol, and timolol.

Class III

This class of drugs predominantly blocks potassium channels (such as I_{Kr}) and prolongs repolarization. Included are sotalol, amiodarone, dronedarone, and ibutilide.

Class IV

This class of drugs predominantly blocks the slow calcium channel (I_{CaL})—verapamil, diltiazem, nifedipine, and others (felodipine blocks I_{CaT}).

**TABLE 35-1** Actions of Drugs Used for the Treatment of Arrhythmias

DRUG	Channels					Receptors				Pumps	Predominant Clinical Effects

*With a background of sympathetic activity.

dV/dt = rate of rise of action potential; MDP = maximum diastolic potential; ERP = effective refractory period (longest S₁-S₂ interval at which S₂ fails to produce a response); CV = conduction velocity; PF = Purkinje fiber; SN Auto = sinus nodal automaticity; Contr = contractility; SI Curr = slow inward current.

Antiarrhythmic drugs appear to cross the cell membrane and interact with receptors in the membrane channels when the channels are in the rested, activated, or inactivated state (see [Table 35-1](#) and [Chapter 33](#)), and each of these interactions is characterized by different association and dissociation rate constants of a drug on its receptor. Such interactions depend on voltage and time. Transitions among rested, activated, and inactivated states are governed by standard Hodgkin-Huxley-type equations. When the drug is bound (associated) to a receptor site at or very close to the ionic channel (the drug may not actually plug the channel), the channel cannot conduct, even in the activated state.

Use Dependence. Some drugs exert greater inhibitory effects on the upstroke of the action potential at more rapid rates of stimulation and after longer periods of stimulation, a characteristic called use dependence. Use dependence means that depression of V_{max} is greater after the channel has been “used” (i.e., after action potential depolarization rather than after a rest period). Agents in class IB exhibit fast kinetics of onset and offset or use-dependent block of the fast channel; that is, they bind and dissociate quickly from receptors. Class IC drugs have slow kinetics, and class IA drugs are intermediate. With increased time spent in diastole (slower rate), a greater proportion of receptors become drug free, and the drug exerts less effect. Unhealthy cells with reduced (i.e., abnormal) membrane potentials

recover more slowly from drug actions than do healthier cells with more negative (i.e., normal) membrane potentials.

Reverse Use Dependence. Some drugs exert greater effects at slow rates than at fast rates, a property known as reverse use dependence. This is particularly true for drugs that lengthen repolarization. The QT interval becomes more prolonged at slow rather than at fast rates. This effect is not what the ideal antiarrhythmic agent would do because prolongation of refractoriness should be increased at fast rates to interrupt or to prevent a tachycardia and should be minimal at slow rates to avoid precipitation of torsades de pointes.

Mechanisms of Arrhythmia Suppression. Given the fact that enhanced automaticity, triggered activity, or reentry can cause cardiac arrhythmias (see Chapter 33), mechanisms by which antiarrhythmic agents suppress arrhythmias can be postulated (see Table 35-2). Antiarrhythmic agents can slow the spontaneous discharge frequency of an automatic pacemaker by depressing the slope of diastolic depolarization, shifting the threshold voltage toward zero, or hyperpolarizing the resting membrane potential. Mechanisms whereby different drugs suppress normal or abnormal automaticity may not be the same. In general, however, most antiarrhythmic agents in therapeutic doses depress the automatic firing rate of spontaneously discharging ectopic sites while minimally affecting the discharge rate of the normal sinus node. Slow channel blockers such as verapamil, beta blockers such as propranolol, and some antiarrhythmic agents such as amiodarone also depress spontaneous discharge of the sinus node, whereas drugs that exert vagolytic effects, such as disopyramide and quinidine, can increase the sinus discharge rate. Drugs can also suppress early or delayed afterdepolarizations and eliminate triggered arrhythmias related to these mechanisms.

Reentry depends critically on the interrelationships between refractoriness and conduction velocity, the presence of unidirectional block in one of the pathways, and other factors that influence refractoriness and conduction, such as excitability (see Chapter 33). An antiarrhythmic agent can stop ongoing reentry that is already present or prevent it from starting if the drug depresses or, alternately, improves conduction. For example, improving conduction can (1) eliminate a unidirectional block so that reentry cannot begin or (2) facilitate conduction in the reentrant loop so that the returning wave front reenters too quickly, encounters cells that are still refractory, and is extinguished. A drug that depresses conduction can transform a unidirectional block into a bidirectional block and thus terminate reentry or prevent it from starting by creating an area of complete block in the reentrant pathway. Conversely, a drug that slows conduction without producing block or lengthening refractoriness significantly can promote reentry. Finally, most antiarrhythmic agents share the ability to prolong refractoriness relative to their effects on APD; that is, the ratio of the effective refractory period (ERP) to APD exceeds 1.0. If a drug prolongs the refractoriness of fibers in the reentrant pathway, the pathway may not recover excitability in time to be depolarized by the reentering impulse, and reentrant propagation ceases. The different types of reentry (see Chapter 33) influence the effects and effectiveness of a drug.

In considering the properties of a drug, it is important that the situation or model from which conclusions are drawn be defined with care. Electrophysiologic, hemodynamic, autonomic, pharmacokinetic, and adverse effects may all differ in normal subjects as compared with patients, in normal tissue as compared with abnormal tissue, in cardiac muscle as compared with specialized conduction fibers, and in atrium as opposed to ventricular muscle (Table 35-4).

Drug Metabolites. Drug metabolites can add to or alter the effects of the parent compound by exerting similar actions, competing with the parent compound, or mediating drug toxicity. Quinidine has at least four active metabolites but none with a potency exceeding that of the parent drug and none implicated in causing torsades de pointes. About 50% of procainamide is metabolized to *N*-acetylprocainamide (NAPA), which prolongs repolarization and is a less effective antiarrhythmic drug but competes with procainamide for renotubular secretory sites and can increase the parent drug's elimination half-life. Lidocaine's metabolite can compete with lidocaine for sodium channels and partially reverse block produced by lidocaine.

Pharmacogenetics. Genetically determined metabolic pathways account for many of the differences in patients' responses to some drugs (see Chapter 9).² The genetically determined activity of hepatic *N*-acetyltransferase regulates the development of antinuclear antibodies and lupus syndrome in response to procainamide. Slow acetylators phenotypes appear to be more prone than rapid acetylators to the development of lupus. The enzyme cytochrome P-450 (CYP450) is needed to metabolize propafenone, to hydroxylate several beta

blockers, and to biotransform flecainide. Lack of this enzyme (in $\approx 7\%$ of patients) reduces metabolism of the parent compound and thereby leads to increased plasma concentrations of the parent drug and reduced concentrations of metabolites. Propafenone is metabolized by CYP450 to a compound with slightly less antiarrhythmic and beta-adrenergic blocking effects, as well as fewer central nervous system side effects. Thus, poor metabolizers may experience more heart rate slowing and neurotoxicity than extensive metabolizers do.

Drugs such as rifampin, phenobarbital, and phenytoin induce the synthesis of larger amounts of CYP450, which leads to lower concentrations of the parent drugs because of extensive metabolism, whereas erythromycin, clarithromycin, fluoxetine, and grapefruit juice inhibit enzyme activity, which leads to accumulation of the parent compound. Cisapride, a gastric motility agent, blocks the delayed rectifier current I_{Kr} , but does not prolong the QT interval significantly in most patients because of extensive metabolism. In patients who take an inhibitor of CYP450 (such as erythromycin) along with cisapride, the latter drug could accumulate and lead to QT prolongation and torsades de pointes.

Clinical Use

In treating cardiac rhythm disorders, most drugs are given on a daily basis (in one to three doses) to prevent episodes from occurring or, in some cases of atrial fibrillation, to control the ventricular rate. Efficacy can be judged in various ways, depending on the clinical circumstances. Symptom reduction (in the case of benign arrhythmias, such as most premature ventricular complexes [PVCs]) and electrocardiographic monitoring (long-term or event; see Chapter 34) are useful; electrophysiologic studies (EPSs) have been used in the past, with suppression of induction of electrical arrhythmia being the goal. However, this is rarely used currently. Interrogation of implanted device memory can also provide an indicator of the success of drug therapy.

In some patients, tachycardia episodes are infrequent enough (months between occurrences) and symptoms mild enough that reactive drug administration is more reasonable than chronic daily dosing. In this setting a patient takes a medication only after an episode has started in the hope that the tachycardia will terminate in response to the drug and a visit to a physician's office or emergency department can be avoided. This "pill in the pocket" strategy has worked well for some patients with atrial fibrillation who have been given one of various medications orally in a monitored setting to ensure safety, as well as efficacy, before allowing self-medication at home or elsewhere.

Side Effects

Antiarrhythmic drugs produce one group of side effects related to excessive dosage and plasma concentrations that result in both noncardiac (e.g., neurologic defects) and cardiac (e.g., heart failure, some arrhythmias) toxicity and another group of side effects unrelated to plasma concentrations, which is termed *idiosyncratic*. Examples of the latter include amiodarone-induced pulmonary fibrosis and some arrhythmias, such as quinidine-induced torsades de pointes, which can occur in individuals with a forme fruste of long-QT syndrome (i.e., normal QT interval at rest but markedly prolonged interval in the presence of certain medications; see Chapters 9 and 32). In the future, it is likely that genetic differences will explain many idiosyncratic reactions.

Proarrhythmia

Drug-induced or drug-exacerbated cardiac arrhythmias (proarrhythmia) constitute a major clinical problem. Proarrhythmia can be manifested as an increase in frequency of a preexisting arrhythmia, sustaining of a previously nonsustained arrhythmia (even making it incessant), or development of arrhythmias that the patient has not previously experienced. Electrophysiologic mechanisms are probably related to prolongation of repolarization or an increase in its transmural dispersion, development of early afterdepolarizations with resultant torsades de pointes, and alterations in reentry pathways to initiate or to sustain tachyarrhythmias (see Chapter 33). Proarrhythmic events can occur in as many as 5% to 10% of patients receiving antiarrhythmic agents. Heart failure increases this risk.

TABLE 35-4 Clinical Use Information for Antiarrhythmic Agents

Usual Dosage Ranges										
DRUG	INTRAVENOUS (mg)		ORAL (mg)		TIME TO PEAK PLASMA CONCENTRATION (ORAL) (hr)	EFFECTIVE SERUM OR PLASMA CONCENTRATION (μg/mL)	HALF-LIFE (hr)	BIOAVAILABILITY (%)	MAJOR ROUTE OF ELIMINATION	PREGNANCY CLASS
	Loading	Maintenance	Loading	Maintenance						
Quinidine	6-10 mg/kg at 0.3-0.5 mg/kg/min	—	800-1000	300-600 q6h	1.5-3.0	3-6	5-9	60-80	Liver	C

*Intravenous use investigational or unavailable in the United States.

Results presented may vary according to doses, disease state, and IV or oral administration.

Pregnancy class: A = controlled studies show no fetal risk; B = no controlled studies, but no evidence of fetal risk; fetal harm unlikely; C = fetal risk cannot be excluded; drug should be used only if potential benefits outweigh potential risk; D = definite fetal risk; drug should be avoided unless in a life-threatening situation or safer alternatives do not exist; X = contraindicated in pregnancy
N/A = not applicable.

Reduced left ventricular function, treatment with digitalis and diuretics, and a longer pretreatment QT interval characterize patients who experience drug-induced ventricular fibrillation (VF). The more commonly known proarrhythmic events occur within several days of beginning drug therapy or changing dosage and are represented by such developments as incessant VT, long-QT syndrome, and torsades de pointes. However, in CAST (Cardiac Arrhythmia Suppression Trial), researchers found that encainide and flecainide reduced spontaneous ventricular arrhythmias but were associated with a total mortality of 7.7%, as opposed to 3.0% in the group receiving placebo. Deaths were equally distributed throughout the treatment period, thus raising the important consideration that another type of proarrhythmic response can occur some time after the beginning of drug therapy. Such late proarrhythmic effects may be related to drug-induced exacerbation of the regional myocardial conduction delay caused by ischemia and to heterogeneous drug concentrations that can promote reentry. In coming years, a candidate antiarrhythmic compound's potential for proarrhythmia may be modeled computationally or tested in stem cells.³

The availability of catheter ablation (see later) and implantable devices (pacemakers and ICDs; see Chapter 36) to treat a wide variety of arrhythmias has largely relegated drug therapy to a secondary role in the treatment of serious arrhythmias. Drugs are still useful to prevent or to decrease the frequency of recurrences in patients who have relatively infrequent episodes of benign tachycardias, those who have had incomplete success with catheter ablation procedures, and patients with an ICD to decrease the frequency of shocks because of supraventricular or ventricular arrhythmias.

Antiarrhythmic Agents

Class IA Agents

Quinidine

Quinidine and quinine are isomeric alkaloids isolated from cinchona bark.⁴ Although quinidine shares the antimalarial, antipyretic, and vagolytic actions of quinine, only quinidine has electrophysiologic effects. It blocks several channels (rapid inward sodium channel, I_{Kr} , I_{to} , and to a lesser extent, the slow inward calcium channel, I_{Ks} , and the adenosine triphosphate (ATP)-sensitive potassium current [$I_{K(ATP)}$]).

Electrophysiologic Actions. Quinidine exerts little effect on automaticity of the normal sinus node but suppresses automaticity in normal Purkinje fibers (Table 35-5; see also Tables 35-1, 35-2, and 35-3). In patients with sick sinus syndrome, quinidine can depress sinus node automaticity. Quinidine produces early afterdepolarizations in experimental preparations and in humans, which may be responsible for torsades de pointes. Because of its significant anticholinergic effect and the reflex sympathetic stimulation resulting from alpha-adrenergic blockade, which causes peripheral vasodilation, quinidine can reflexly increase the sinus node discharge rate and improve atrioventricular (AV) nodal conduction. Quinidine prolongs repolarization, an effect that is more prominent at slow heart rates (reverse use dependence) because of block of I_{Kr} (as well as enhancing the late Na current). Faster rates result in more block of sodium channels and less unblocking because of a smaller percentage of time spent in a polarized state (use dependence). Isoproterenol can modulate the effects of quinidine on reentrant circuits in humans. Quinidine at higher doses inhibits the late Na current. As noted, quinidine blocks the transient outward current I_{to} , which is probably why it is effective in suppressing ventricular arrhythmias in Brugada syndrome (see Chapter 9).

Hemodynamic Effects. Quinidine induces vasodilation by blocking alpha-adrenergic receptors and can cause significant hypotension. It does not result in significant direct myocardial depression.

Pharmacokinetics. Plasma quinidine concentrations peak at approximately 3 to 4 hours after an oral dose of a quinidine gluconate preparation (see Table 35-4). Quinidine can be given intravenously if it is infused slowly, but intramuscular dosing should be avoided. Approximately 80% of plasma quinidine is protein bound, especially to alpha₂-acid glycoprotein. Both the liver and the kidneys remove quinidine; dose adjustments may be made to achieve appropriate serum concentrations. Its elimination half-life is 5 to 8 hours after oral administration. Quinidine's effect on repolarization and its overall efficacy vary directly with left ventricular function; at the same serum concentration, the QT interval is longer in women than in men.

DOSAGE AND ADMINISTRATION. The usual oral dose of quinidine sulfate for an adult is 300 to 600 mg four times daily, which results in a steady-state level within about 24 hours (see Table 35-4). A loading dose of 600 to 1000 mg produces an earlier effective concentration. Oral doses of the gluconate are about 30% higher than those of the sulfate. Important interactions with other drugs occur.

INDICATIONS. Quinidine is a versatile antiarrhythmic agent that was used previously to treat premature supraventricular and ventricular complexes and sustained tachyarrhythmias. However, because of its side effect profile and potential for causing torsades de pointes, as well as its limited usefulness in preventing VT and VF in most applications, its use has decreased greatly. In recent years, however, there has been an increase in interest in quinidine for treating primary VF, ventricular arrhythmias in patients with Brugada syndrome⁵ (see Chapter 32), and short-QT syndrome.⁶ Because it crosses the placenta, quinidine can be used to treat arrhythmias in the fetus.

ADVERSE EFFECTS. The most common adverse effects of chronic oral quinidine therapy are gastrointestinal and include nausea, vomiting, diarrhea, abdominal pain, and anorexia (milder with the gluconate form). Central nervous system toxicity includes tinnitus, hearing loss, visual disturbances, confusion, delirium, and psychosis (cinchonism). Allergic reactions include rash, fever, immune-mediated thrombocytopenia, hemolytic anemia, and rarely, anaphylaxis. Side effects may preclude long-term administration of quinidine in 30% to 40% of patients.

Quinidine can slow cardiac conduction, sometimes to the point of block, which is manifested as prolongation of the QRS duration or as sinoatrial or AV nodal conduction disturbances. Quinidine can produce syncope in 0.5% to 2.0% of patients, most often the result of a self-terminating episode of torsades de pointes. Quinidine prolongs the QT interval in most patients, regardless of whether ventricular arrhythmias occur, but significant QT prolongation (QT interval of 500 to 600 milliseconds) is often a characteristic of patients with quinidine-related syncope, who may have a genetic predisposition underlying such a response (see Chapter 9). Many of these patients are also receiving digitalis or diuretics or have hypokalemia; women are more susceptible than men. Importantly, syncope is unrelated to plasma concentrations of quinidine or the duration of therapy, although most episodes occur within the first 2 to 4 days of therapy, often after conversion of atrial fibrillation to sinus rhythm (for this reason the drug should not be taken on an intermittent basis). Therapy requires immediate discontinuation of use of the drug and avoidance of other drugs that have similar pharmacologic effects because cross-sensitivity exists in some patients. Magnesium given intravenously (2 g over a period of 1 to 2 minutes, followed by an infusion of 3 to 20 mg/min) is the initial drug treatment of choice. Atrial or ventricular pacing can be used to suppress the ventricular tachyarrhythmia, perhaps by suppressing early afterdepolarizations. When pacing is not available, isoproterenol can be given with caution. The arrhythmia gradually dissipates as quinidine is cleared and the QT interval returns to baseline.

Drugs that induce hepatic enzyme production, such as phenobarbital and phenytoin, can shorten the duration of action of quinidine by increasing its rate of elimination. Quinidine can increase plasma concentrations of flecainide by inhibiting the CYP450 enzyme system. Quinidine may elevate serum digoxin concentrations by decreasing its clearance and volume of distribution and the affinity of tissue receptors.

Procainamide

Electrophysiologic Actions. The cardiac actions of procainamide on automaticity, conduction, excitability, and membrane responsiveness resemble those of quinidine (see Tables 35-1, 35-2, 35-3, and 35-5). Procainamide predominantly blocks the inactivated state of I_{Na} . It also blocks I_{Kr} and $I_{K(ATP)}$. Like quinidine, procainamide usually prolongs the ERP more than it prolongs the APD and thus may prevent reentry. Procainamide exerts the least anticholinergic effects among type IA drugs. It does not affect normal sinus node automaticity. In vitro, procainamide decreases abnormal automaticity, with less effect on triggered activity or catecholamine-enhanced normal automaticity. The electrophysiologic effects of NAPA, the major metabolite of procainamide, differ from those of the parent compound. NAPA, a K^+

TABLE 35-5 In Vivo Electrophysiological Characteristics of Antiarrhythmic Drugs

Results presented may vary according to tissue type, drug concentration, and autonomic tone.

↑ = increase; ↓ = decrease; 0 = no change; 0 ↑ or 0 ↓ = slight or inconsistent increase or decrease; A = atrium; AVN = AV node; HPS = His-Purkinje system; V = ventricle; AH = atrio-His interval (an index of AV nodal conduction); HV = His-ventricular interval (an index of His-Purkinje conduction); ERP = effective refractory period (longest S₁-S₂ interval at which S₂ fails to produce a response).

channel blocker (I_{Kr}), exerts a class III action and prolongs the APD of ventricular muscle and Purkinje fibers in a dose-dependent manner. High levels can produce early afterdepolarizations, triggered activity, and torsades de pointes.

Hemodynamic Effects. Procainamide can depress myocardial contractility in high concentrations. It does not produce alpha blockade but can result in peripheral vasodilation, possibly through anti-sympathetic effects on the brain or spinal cord, which can impair cardiovascular reflexes.

Pharmacokinetics. Oral administration produces a peak plasma concentration in around 1 hour. Approximately 80% of oral procainamide is bioavailable; the overall elimination half-life of procainamide is 3 to 5 hours, with 50% to 60% of the drug being eliminated by the kidneys and 10% to 30% by hepatic metabolism (see Table 35-4). The drug is acetylated to NAPA, which is excreted almost exclusively by the kidneys. As renal function decreases and in patients with heart failure, NAPA levels increase and, because of the risk for serious cardiotoxicity, need to be carefully monitored in these situations. NAPA has an elimination half-life of 7 to 8 hours, but the half-life exceeds 10 hours if high doses of procainamide are used. Increased age, congestive heart failure, and reduced creatinine clearance lower the clearance of procainamide and necessitate a reduced dosage.

DOSAGE AND ADMINISTRATION. Procainamide can be given by the oral, intravenous, or intramuscular route to achieve plasma concentrations in the range of 4 to 10 mg/mL and produce an antiarrhythmic effect (see Table 35-4). Several intravenous regimens have been used to administer procainamide; 25 to 50 mg can be given during a 1-minute period and then repeated every 5 minutes until the arrhythmia has been controlled, hypotension results, or the QRS complex is prolonged more than 50%. Doses of 10 to 15 mg/kg administered a rate of at 50 mg/min can also be used. With this method, the plasma concentration falls rapidly during the first 15 minutes after the loading dose, with parallel effects on refractoriness and conduction. A

constant-rate intravenous infusion of procainamide can be given at a dosage of 2 to 6 mg/min, depending on the patient's response.

Oral administration of procainamide requires a 3- to 4-hour dosing interval at a total daily dose of 2 to 6 g, with a steady-state concentration being reached within 1 day. When a loading dose is used, it should be twice the maintenance dose. Frequent dosing is required because of its short elimination half-life in normal subjects. For the extended-release forms of procainamide, dosing is at 6- to 12-hour intervals. Procainamide is well absorbed after intramuscular injection, with almost 100% of the dose bioavailable.

INDICATIONS. Procainamide is used to treat both supraventricular and ventricular arrhythmias in a manner comparable to that of quinidine. Although both drugs have similar electrophysiologic actions, either drug can effectively suppress a supraventricular or ventricular arrhythmia that is resistant to the other drug. Procainamide can be used to convert recent-onset atrial fibrillation to sinus rhythm. As with quinidine, prior treatment with beta or calcium channel blockers is recommended to prevent acceleration of the ventricular response during atrial flutter or fibrillation after procainamide therapy. Procainamide can block conduction in the accessory pathway of patients with Wolff-Parkinson-White syndrome and can be used in patients with atrial fibrillation and a rapid ventricular response related to conduction over the accessory pathway. It can produce His-Purkinje block (see Fig. 34-8) and is sometimes administered during an EPS to stress the His-Purkinje system and evaluate the need for a pacemaker. However, it should be used with caution in patients with evidence of His-Purkinje disease (bundle branch block) in whom a ventricular pacemaker is not readily available. Procainamide is more effective than lidocaine in acutely terminating sustained VT. Most consistently, procainamide slows the VT rate, a change correlated with the increase in QRS duration. The drug also has diagnostic application when given intravenously (10 mg/kg over

a 5- to 10-minute period). In patients with suspected Brugada syndrome who have normal findings on a resting electrocardiogram (ECG), drug infusion may result in the characteristic “Brugada sign,” whereas in patients with Wolff-Parkinson-White syndrome, the drug may cause sudden loss of preexcitation, a finding indicative of an accessory pathway with a long refractory period and suggesting low risk for a dangerously rapid ventricular rate during atrial fibrillation. Evidence for the latter point is mixed, however.

ADVERSE EFFECTS. Noncardiac adverse effects from administration of procainamide include rash, myalgia, digital vasculitis, and Raynaud phenomenon. Fever and agranulocytosis may be the result of hypersensitivity reactions, and the white blood cell and differential counts should be assessed at regular intervals. Gastrointestinal side effects are less frequent than with quinidine, and adverse central nervous system side effects are less frequent than with lidocaine. Toxic concentrations of procainamide can diminish myocardial performance and promote hypotension. Various conduction disturbances or ventricular tachyarrhythmias that are similar to those produced by quinidine can occur. NAPA can cause QT prolongation and torsades de pointes. In the absence of sinus node disease, procainamide does not adversely affect sinus node function. In patients with sinus node dysfunction, however, procainamide can prolong sinus node recovery time and worsen symptoms in some patients with bradycardia-tachycardia syndrome.

Arthralgia, fever, pleuropericarditis, hepatomegaly, and hemorrhagic pericardial effusion with tamponade have been described in a systemic lupus erythematosus (SLE)-like syndrome related to procainamide administration. The syndrome occurs more frequently and earlier in patients who are slow acetylators of procainamide and is genetically influenced (see Chapter 9). Acetylation of an aromatic amino group on procainamide to form NAPA appears to block the SLE-inducing effect. In 60% to 70% of patients who take procainamide on a chronic basis, antinuclear antibodies develop, with clinical symptoms occurring in 20% to 30%, but this is reversible when use of procainamide is stopped. Positive serologic test results are not necessarily a reason to discontinue drug therapy; however, the development of symptoms or a positive anti-DNA antibody indicates that drug therapy should be discontinued. Corticosteroid administration in these patients may eliminate the symptoms. In this syndrome, in contrast to naturally occurring SLE, the brain and kidneys are spared, and there is no predilection for women.

Disopyramide

Disopyramide has been approved in the United States for oral administration to treat patients with ventricular and supraventricular arrhythmias.

Electrophysiologic Actions. Although it is structurally different from quinidine and procainamide, disopyramide produces similar electrophysiologic effects; it causes use-dependent block of I_{Na} and non-use-dependent block of I_{Kr} (see Tables 35-1, 35-2, 35-3, and 35-5). Disopyramide also inhibits $I_{K,ATP}$; it does not affect calcium-dependent action potentials, except possibly at very high concentrations.

Disopyramide is a muscarinic blocker and can increase the sinus node discharge rate and shorten AV nodal conduction time and refractoriness when the nodes are under cholinergic (vagal) influence. Disopyramide can also slow the sinus node discharge rate by a direct action when given in high concentration and can significantly depress sinus node activity in patients with sinus node dysfunction. It exerts greater anticholinergic effects than quinidine does and does not appear to affect alpha or beta adrenoceptors. The drug prolongs atrial and ventricular refractory periods, but its effect on AV nodal conduction and refractoriness is not consistent. Disopyramide prolongs His-Purkinje conduction time, but infra-His block rarely occurs. It can be administered safely to patients who have first-degree AV delay and narrow QRS complexes.

Hemodynamic Effects. Disopyramide suppresses ventricular systolic performance and is a mild arterial vasodilator. The drug should generally be avoided in patients with reduced left ventricular systolic function because they tolerate its negative inotropic effects poorly.

Pharmacokinetics. Disopyramide is 80% to 90% absorbed, with a mean elimination half-life of 8 to 9 hours in healthy volunteers but almost 10 hours in patients with heart failure (see Table 35-4). Renal

insufficiency prolongs its elimination time. Thus, in patients with renal, hepatic, or cardiac insufficiency, loading and maintenance doses need to be reduced. Peak blood levels after oral administration occur in 1 to 2 hours. Approximately 50% of an oral dose is excreted unchanged in urine, with around 30% occurring as the mono-*N*-dealkylated metabolite. The metabolites appear to exert less effect than the parent compound does. Erythromycin inhibits its metabolism.

DOSAGE AND ADMINISTRATION. Doses are generally 100 to 200 mg orally every 6 hours, with a range of 400 to 1200 mg/day (see Table 35-4). A controlled-release preparation can be given as 200 to 300 mg every 12 hours.

INDICATIONS. Disopyramide appears to be comparable to quinidine and procainamide in reducing the frequency of PVCs and effectively preventing recurrence of VT in selected patients. Disopyramide has been combined with other drugs, such as mexiletine, to treat patients who do not respond or respond only partially to one drug.

Disopyramide helps prevent recurrence of atrial fibrillation after successful cardioversion as effectively as quinidine does and may terminate atrial flutter. In treating patients with atrial fibrillation, particularly atrial flutter, the ventricular rate must be controlled before disopyramide is administered, or the combination of a decrease in atrial rate with vagolytic effects on the AV node can result in 1:1 AV conduction during atrial flutter (see Chapter 38). Disopyramide may be useful in preventing episodes of neurally mediated syncope. It has been used in patients with hypertrophic cardiomyopathy.

ADVERSE EFFECTS. Three types of adverse effects follow disopyramide administration. The most common effects are related to the drug's potent parasympatholytic properties and include urinary hesitancy or retention, constipation, blurred vision, closed-angle glaucoma, and dry mouth. Symptoms are less with the sustained-release form. Second, disopyramide can produce ventricular tachyarrhythmias that are commonly associated with QT prolongation and torsades de pointes. Cross-sensitization to both quinidine and disopyramide occurs in some patients, and torsades de pointes can develop while receiving either drug. When drug-induced torsades de pointes occurs, agents that prolong the QT interval should be used cautiously or not at all. Finally, disopyramide can reduce contractility of the normal ventricle, but the depression of ventricular function is much more pronounced in patients with preexisting ventricular failure. Rarely, cardiovascular collapse can result.

Ajmaline

Ajmaline, a rauwolfia derivative, has been used extensively to treat patients with ventricular and supraventricular arrhythmias in Europe and Asia but is not available in the United States.

Electrophysiologic Actions. Like other type IA drugs, ajmaline produces use-dependent block of I_{Na} ; it also weakly blocks I_{Kr} . The drug has mild anticholinergic activity (see Tables 35-1, 35-2, 35-3, and 35-5).

Hemodynamic Effects. Ajmaline mildly suppresses ventricular systolic performance but does not affect peripheral resistance. It also inhibits platelet activity more potently than aspirin does.

Pharmacokinetics, Dosage, and Administration. Ajmaline is well absorbed with a mean elimination half-life of 13 minutes in most patients, thus making it poorly suited to long-term oral use. The dose for termination of acute arrhythmia is generally 50 mg intravenously infused over a period of 1 to 2 minutes (see Table 35-4).

Indications. Although it is useful for terminating SVTs by intravenous infusion, other medications have largely supplanted ajmaline for this purpose. The drug's use has evolved to that of a diagnostic tool. When administered intravenously at doses of 50 mg over a 3-minute period, or 10 mg/min, to a total dose of 1 mg/kg, ajmaline can have the following effects: (1) delta wave disappearance in patients with Wolff-Parkinson-White syndrome (indicating an accessory pathway anterograde ERP longer than 250 milliseconds); (2) ST-T abnormalities and interventricular conduction blocks in patients with occult chagasic cardiomyopathy; (3) heart block in patients with bundle branch block and syncope, but in whom no rhythm disturbance had been discovered; and (4) right precordial ST elevation in patients with suspected Brugada syndrome in whom findings on the resting ECG are normal. It is in this last setting that ajmaline is used most frequently.

Adverse Effects. Ajmaline can produce mild anticholinergic side effects, as well as mild depression of left ventricular systolic function, and can worsen AV conduction in patients with His-Purkinje disease. Rare occurrences of torsades de pointes have been reported. Ajmaline can cause an increase in the defibrillation threshold.

Class IB Agents

Lidocaine

Electrophysiologic Actions. Lidocaine blocks I_{Na} predominantly in the open or possibly inactivated state. It has rapid onset and offset kinetics and does not affect normal sinus node automaticity in usual doses but does depress other normal and abnormal forms of automaticity, as well as early and late afterdepolarizations in Purkinje fibers in vitro (see [Tables 35-1, 35-2, 35-3, and 35-5](#)). Lidocaine has only a modest depressant effect on Vmax; however, faster rates of stimulation, reduced pH, increased extracellular K^+ concentration, and reduced membrane potential (changes that can result from ischemia) increase the ability of lidocaine to block I_{Na} . Lidocaine can convert areas of unidirectional block into bidirectional block during ischemia and inhibit the development of VF by preventing fragmentation of organized large wave fronts into heterogeneous wavelets.

Except in very high concentrations, lidocaine does not affect slow-channel-dependent action potentials despite its moderate suppression of the slow inward current. Lidocaine has little effect on atrial fibers and does not affect conduction in accessory pathways. Depressed automaticity or conduction can develop in patients with preexisting sinus node dysfunction, abnormal His-Purkinje conduction, or junctional or ventricular escape rhythms. Part of its effects may involve inhibition of cardiac sympathetic nerve activity.

Hemodynamic Effects. Clinically significant adverse hemodynamic effects are rarely noted at the usual drug concentrations unless left ventricular function is severely impaired.

Pharmacokinetics. Lidocaine is used only parenterally because oral administration results in extensive first-pass hepatic metabolism and unpredictable low plasma levels, as well as excessive metabolites that can produce toxicity (see [Table 35-4](#)). Hepatic metabolism of lidocaine depends on hepatic blood flow; severe hepatic disease or reduced hepatic blood flow, as in heart failure or shock, can markedly decrease the rate of lidocaine metabolism. Beta adrenoceptor blockers can decrease hepatic blood flow and increase the serum concentration of lidocaine. Prolonged infusion can reduce lidocaine clearance. Its elimination half-life averages 1 to 2 hours in normal subjects, longer than 4 hours in patients after uncomplicated myocardial infarction, longer than 10 hours in patients after myocardial infarction complicated by heart failure, and even longer in the presence of cardiogenic shock. Maintenance doses should be reduced by a third to a half in patients with low cardiac output. Lidocaine is 50% to 80% protein bound.

DOSAGE AND ADMINISTRATION. Although lidocaine can be given intramuscularly, the intravenous route is most commonly used, with an initial bolus of 1 to 2 mg/kg body weight at a rate of 20 to 50 mg/min and a second injection of half the initial dose 20 to 40 minutes later to maintain the therapeutic concentration (see [Table 35-4](#)).

If the initial bolus of lidocaine is ineffective, up to two more boluses of 1 mg/kg may be administered at 5-minute intervals. Patients who require more than one bolus to achieve a therapeutic effect have arrhythmias that respond only to higher lidocaine plasma concentrations, and a higher maintenance dose may be necessary to sustain these higher concentrations. Maintenance infusion rates in the range of 1 to 4 mg/min produce steady-state plasma levels of 1 to 5 mg/mL in patients with uncomplicated myocardial infarction, but these rates must be reduced during heart failure or shock because of the concomitant reduced hepatic blood flow. Higher doses are unlikely to provide additional benefit but do increase the risk for toxicity.

INDICATIONS. Lidocaine has moderate efficacy against ventricular arrhythmias of diverse causes; it is generally ineffective against supraventricular arrhythmias and rarely terminates monomorphic VT. Although once commonly used in an attempt to prevent VF in the first 2 days after acute myocardial infarction, its efficacy was not great, and because it can produce side effects and a possible increase in the risk for the development of asystole, such use is not recommended. Lidocaine has been effective in patients after coronary revascularization and in those resuscitated from out-of-hospital VF,

although amiodarone has been shown to yield higher rates of survival, at least to hospital admission.

ADVERSE EFFECTS. The most commonly reported adverse effects of lidocaine are dose-related manifestations of central nervous system toxicity: dizziness, paresthesias, confusion, delirium, stupor, coma, and seizures. Occasional sinus node depression and His-Purkinje block have been reported. Rarely, lidocaine can cause malignant hyperthermia.

Mexiletine

Mexiletine, a local anesthetic congener of lidocaine with anticonvulsant properties, is used for the oral treatment of patients with symptomatic ventricular arrhythmias.

Electrophysiologic Actions. Mexiletine is similar to lidocaine in many of its electrophysiologic actions. In vitro, mexiletine shortens the APD and ERP of Purkinje fibers and, to a lesser extent, ventricular muscle. It depresses the Vmax of phase 0 by blocking I_{Na} , especially at faster rates, and depresses the automaticity of Purkinje fibers but not of the normal sinus node. Its onset and offset kinetics are rapid. Hypoxia or ischemia can increase its effects (see [Tables 35-1, 35-2, 35-3, and 35-5](#)).

Mexiletine can result in severe bradycardia and abnormal sinus node recovery time in patients with sinus node disease, but not in those with a normal sinus node. It does not affect AV nodal conduction and can depress His-Purkinje conduction, but not greatly, unless conduction was abnormal initially. Mexiletine does not appear to affect human atrial muscle. It does not affect the QT interval. It has been used in treating a variety of other disorders, including erythromelalgia (red, painful extremities) in children and myotonia.

Hemodynamic Effects. Mexiletine exerts no major hemodynamic effects on ventricular contractile performance or peripheral resistance.

Pharmacokinetics. Mexiletine is rapidly and almost completely absorbed after oral ingestion by volunteers, with peak plasma concentrations being attained in 2 to 4 hours (see [Table 35-4](#)). Its elimination half-life is approximately 10 hours in healthy subjects but 17 hours in patients after myocardial infarction. Therapeutic plasma levels of 0.5 to 2 mg/mL are maintained by oral doses of 200 to 300 mg every 6 to 8 hours. Absorption with less than a 10% first-pass hepatic effect occurs in the upper part of the small intestine and is delayed and incomplete in patients receiving narcotics or antacids. Approximately 70% of the drug is protein bound. The apparent volume of distribution is large because of extensive tissue uptake. Normally, mexiletine is eliminated metabolically by the liver, with less than 10% being excreted unchanged in urine. Doses should be reduced in patients with cirrhosis or left ventricular failure. Renal clearance of mexiletine decreases as urinary pH increases. Its known metabolites exert no electrophysiologic effects. Metabolism can be increased by phenytoin, phenobarbital, and rifampin and can be reduced by cimetidine.

DOSAGE AND ADMINISTRATION. The recommended starting dose is 200 mg orally every 8 hours when rapid arrhythmia control is not essential (see [Table 35-4](#)). Doses may be increased or decreased by 50 to 100 mg every 2 to 3 days and are better tolerated when given with food. The total daily dose should not exceed 1200 mg. In some patients, administration every 12 hours can be effective.

INDICATIONS. Mexiletine is a moderately effective antiarrhythmic agent for the treatment of acute and chronic ventricular tachyarrhythmias, but not SVTs. Success rates vary from 6% to 60% and can be increased in some patients if mexiletine is combined with other drugs such as procainamide, beta blockers, quinidine, disopyramide, propafenone, or amiodarone. Most studies show no clear superiority of mexiletine over other class I agents. Mexiletine may be very useful in children with congenital heart disease and serious ventricular arrhythmias. In treating patients with a long QT interval, mexiletine may be safer than drugs that increase the QT interval further, such as quinidine. Limited experience in treating subsets of patients with long-QT syndrome (LQT3, which is related to the *SCN5A* gene for the cardiac sodium channel) suggests a beneficial role (see [Chapter 32](#)).

ADVERSE EFFECTS. Up to 40% of patients may require a change in dose or discontinuation of mexiletine therapy as a result of adverse effects, including tremor, dysarthria, dizziness, paresthesia, diplopia, nystagmus, confusion, nausea, vomiting, and dyspepsia. Cardiovascular side effects are rare but include hypotension, bradycardia, and

exacerbation of arrhythmia. The adverse effects of mexiletine appear to be dose related, and toxic effects occur at plasma concentrations only slightly higher than therapeutic levels. Therefore, effective use of this antiarrhythmic drug requires careful titration of dose and monitoring of plasma concentration. Lidocaine should be avoided or the dose reduced in patients receiving mexiletine.

Phenytoin

Phenytoin was used originally to treat seizure disorders. Its value as an antiarrhythmic agent remains limited.

Electrophysiologic Actions. Phenytoin effectively abolishes abnormal automaticity caused by digitalis-induced delayed afterdepolarizations in cardiac Purkinje fibers and suppresses certain digitalis-induced arrhythmias in humans (see [Tables 35-1, 35-2, 35-3, and 35-5](#)). The rate of rise of action potentials initiated early in the relative refractory period is increased, as is membrane responsiveness, which possibly reduces the chance of impaired conduction and block. Phenytoin minimally affects the sinus discharge rate and AV conduction in humans. Some of phenytoin's antiarrhythmic effects may be neurally mediated because it can modulate both sympathetic and vagal efferent activity. It has no peripheral cholinergic- or beta-adrenergic blocking actions and minimal hemodynamic effect.

Pharmacokinetics. The pharmacokinetics of phenytoin is less than ideal. Absorption after oral administration is incomplete and varies with the brand of drug. Plasma concentrations peak 8 to 12 hours after an oral dose; 90% of the drug is protein bound (see [Table 35-4](#)). Phenytoin has limited solubility at physiologic pH, and intramuscular administration is associated with pain, muscle necrosis, sterile abscesses, and variable absorption. Therapeutic serum concentrations of phenytoin (10 to 20 mg/mL) are similar for the treatment of cardiac arrhythmias and epilepsy. Lower concentrations can suppress certain digitalis-induced arrhythmias.

Metabolism. More than 90% of a dose is hydroxylated in the liver to inactive compounds; significant genetically determined variation can occur. The elimination half-time of phenytoin is approximately 24 hours and can be slowed in the presence of liver disease or when it is administered concomitantly with drugs such as warfarin, isoniazid, and phenothiazines, which compete with phenytoin for hepatic enzymes. Because of the large number of medications that can increase or decrease phenytoin levels during chronic therapy, the plasma concentration of phenytoin should be determined frequently when changes are made in other medications. Phenytoin has concentration-dependent kinetics for elimination that can cause unexpected toxicity because disproportionately large changes in plasma concentration can follow dose increases.

Dosage and Administration

To achieve a therapeutic plasma concentration rapidly, 100 mg of phenytoin should be administered intravenously every 5 minutes until the arrhythmia is controlled, 1 g has been given, or adverse side effects result (see [Table 35-4](#)). In general, if phenytoin is going to control the arrhythmia, 700 to 1000 mg suffices. A large central vein should be used to avoid pain and the development of phlebitis produced by the drug's alkalotic vehicle. Orally, phenytoin is given as a loading dose of 1000 mg the first day, 500 mg on the second and third days, and 300 to 400 mg daily thereafter. Maintenance doses can generally be given once daily because of the long half-life of elimination.

Indications

Phenytoin has been used successfully to treat atrial and ventricular arrhythmias caused by digitalis toxicity but is much less effective in treating ventricular arrhythmias in patients with ischemic heart disease or with atrial arrhythmias not caused by digitalis toxicity.

Adverse Effects

The most common manifestations of phenytoin toxicity are central nervous system effects (nystagmus, ataxia, drowsiness, stupor, and coma) and correlate with increases in plasma drug concentration. Nausea, epigastric pain, and anorexia are also relatively common effects of phenytoin. Long-term administration can result in hyperglycemia, hypocalcemia, rash, megaloblastic anemia, gingival hypertrophy, lymph node hyperplasia (a syndrome resembling malignant lymphoma), peripheral neuropathy, pneumonitis, and drug-induced SLE.

Class IC Agents

Flecainide

Flecainide is approved by the U.S. Food and Drug Administration (FDA) to treat patients with life-threatening ventricular arrhythmias, as well as various supraventricular arrhythmias.

Electrophysiologic Actions. Flecainide exhibits marked use-dependent depressant effects on the rapid sodium channel by decreasing V_{max} and has slow onset and offset kinetics (see [Tables 35-1, 35-2, 35-3, and 35-5](#)). Drug dissociation from the sodium channel is slow, with time constants of 10 to 30 seconds (versus 4 to 8 seconds for quinidine and less than 1 second for lidocaine). Thus, marked drug effects can occur at physiologic heart rates. Flecainide shortens the duration of the Purkinje fiber action potential but prolongs it in ventricular muscle, actions that depending on the circumstances, could enhance or reduce electrical heterogeneity and create or suppress arrhythmias. Flecainide profoundly slows conduction in all cardiac fibers and, in high concentrations, inhibits the slow Ca^{2+} channel (see [Chapter 33](#)). Conduction time in the atria, ventricles, AV node, and His-Purkinje system is prolonged. Minimal increases in atrial or ventricular refractoriness or in the QT interval result. Anterograde and retrograde refractoriness in accessory pathways can increase significantly in a use-dependent fashion. Sinus node function remains unchanged in normal subjects but may be depressed in patients with sinus node dysfunction. Flecainide can facilitate or inhibit reentry and may transform atrial fibrillation to flutter. Pacing and defibrillation thresholds are characteristically slightly to significantly increased.

Hemodynamic Effects. Flecainide depresses cardiac performance, particularly in patients with compromised ventricular systolic function, and should be used cautiously or not at all in those with moderate or severe ventricular systolic dysfunction.

Pharmacokinetics. Flecainide is at least 90% absorbed, with peak plasma concentrations being achieved in 3 to 4 hours. Its elimination half-life in patients with ventricular arrhythmias is 20 hours, with 85% of the drug being excreted unchanged or as an inactive metabolite in urine (see [Table 35-4](#)). Its two major metabolites have less potency than the parent drug. Elimination is slower in patients with renal disease and heart failure, and doses should be reduced in these situations. Therapeutic plasma concentrations range from 0.2 to 1.0 mg/mL. Approximately 40% of the drug is protein bound. Increases in serum concentrations of digoxin (15% to 25%) and propranolol (30%) result during coadministration with flecainide. Propranolol, quinidine, and amiodarone may increase flecainide serum concentrations. Five to 7 days of dosing may be required to reach a steady-state concentration in some patients.

DOSAGE AND ADMINISTRATION. The starting dose is 100 mg every 12 hours, increased in increments of 50 mg twice daily, no sooner than every 3 to 4 days, until efficacy is achieved or an adverse effect is noted or to a maximum of 400 mg/day (see [Table 35-4](#)). Cardiac rhythm and QRS duration should be monitored after changes in dose.

INDICATIONS. Flecainide is indicated for the treatment of life-threatening ventricular tachyarrhythmias, SVTs, and paroxysmal atrial fibrillation. Encouraging experimental and early clinical data support its use for catecholaminergic polymorphic VT (see [Chapter 32](#)). Some experts have suggested that therapy should begin in the hospital while the ECG is being monitored because of the possibility of proarrhythmic events (see later). The dosage is adjusted to achieve the desired effect, but the serum concentration should not exceed 1.0 mg/mL. Flecainide is particularly effective in almost totally suppressing PVCs and short runs of nonsustained VT. As with other class I antiarrhythmic drugs, no data from controlled studies indicate that the drug favorably affects survival or sudden cardiac death, and data from CAST have indicated increased mortality in patients with coronary artery disease. Flecainide produces a use-dependent prolongation of VT cycle length, which can improve hemodynamic tolerance. Flecainide is also useful for various SVTs, such as atrial tachycardia (AT), flutter, and atrial fibrillation (including oral loading to terminate episodes acutely). When it is administered chronically, isoproterenol can reverse some of these effects. It is important to slow the ventricular rate before treatment of atrial fibrillation with flecainide to avoid the 1:1 AV conduction of slowed atrial flutter that may result from the effect of flecainide on fibrillation. Flecainide has been used to treat fetal

arrhythmias and arrhythmias in children. Flecainide administration can produce ST elevation in lead V₁, characteristic of Brugada syndrome, in susceptible patients (see Chapter 32) and has been used as a diagnostic tool in persons suspected of having this disorder.

ADVERSE EFFECTS. Proarrhythmic effects are some of the most important adverse effects of flecainide. Its marked slowing of conduction precludes its use in patients with second-degree AV block without a pacemaker and warrants cautious administration in patients with intraventricular conduction disorders. Worsening of existing ventricular arrhythmias or the onset of new ventricular arrhythmias can occur in 5% to 30% of patients, especially in those with preexisting sustained VT, cardiac decompensation, and higher doses of the drug. Failure of the flecainide-related arrhythmia to respond to therapy, including electrical cardioversion-defibrillation, may result in mortality as high as 10% in patients in whom proarrhythmic events develop. Negative inotropic effects can precipitate or worsen heart failure episodes. Patients with sinus node dysfunction may experience sinus arrest, and an increase in the pacing threshold may develop in those with pacemakers. In CAST, patients treated with flecainide had 5.1% mortality or nonfatal cardiac arrest versus 2.3% in the placebo group during a 10-month period. Mortality was highest in those with non-Q-wave infarction, frequent PVCs, and faster heart rates, thus raising the possibility of drug interaction with ischemia and electrical instability. Exercise can amplify the conduction slowing in the ventricle produced by flecainide and in some cases can precipitate a proarrhythmic response. Therefore, exercise testing has been recommended to screen for proarrhythmia (as well as occult ischemia). Central nervous system complaints, including confusion and irritability, represent the most frequent noncardiac adverse effects. The safety of flecainide during pregnancy has not been determined, although as noted previously, it is occasionally used to treat fetal arrhythmias. It is concentrated in breast milk to a level 2.5- to 4-fold higher than in plasma.

Propafenone

Propafenone has been approved by the FDA for the treatment of patients with life-threatening ventricular tachyarrhythmias, as well as atrial fibrillation.

Electrophysiologic Actions. Propafenone blocks the fast sodium current in a use-dependent manner in Purkinje fibers and to a lesser degree in ventricular muscle (see Tables 35-1, 35-2, 35-3, and 35-5). Its use-dependent effects contribute to its ability to terminate atrial fibrillation. Its dissociation constant from the receptor is slow, similar to that of flecainide. Effects are greater in ischemic than in normal tissue and with reduced membrane potentials. Propafenone decreases excitability and suppresses spontaneous automaticity and triggered activity. The drug is a weak blocker of I_{Kr} and beta-adrenergic receptors. Although ventricular refractoriness increases, slowing of conduction is the major effect. Propafenone has several active metabolites that exert electrophysiologic effects. It depresses sinus node automaticity, and the A-H, H-V, PR, and QRS intervals increase, as do the refractory periods of all tissues. The QT interval increases only as a function of increased QRS duration.

Hemodynamic Effects. Propafenone and 5-hydroxypropafenone exhibit negative inotropic properties at high concentrations. In patients with left ventricular ejection fractions exceeding 40%, the negative inotropic effects are well tolerated, but patients with preexisting left ventricular dysfunction and congestive heart failure may have symptomatic worsening of their hemodynamic status.

Pharmacokinetics. With more than 95% of the drug absorbed, the maximum plasma concentration of propafenone is achieved in 2 to 3 hours (see Table 35-4). Systemic bioavailability is dose dependent and ranges from 3% to 40% because of variable presystemic clearance. Bioavailability increases as the dose increases, and the plasma concentration is therefore not linearly related to dose. A 3-fold increase in dosage (300 to 900 mg/day) results in a 10-fold increase in plasma concentration, presumably because of saturation of hepatic metabolic mechanisms. Propafenone is 97% bound to alpha₁-acid glycoprotein, with an elimination half-life of 5 to 8 hours. Maximum therapeutic effects occur at serum concentrations of 0.2 to 1.5 mg/mL. The marked interpatient variability in pharmacokinetics and pharmacodynamics may be the result of genetically determined differences

in metabolism (see Chapter 9). Approximately 7% of the population are poor metabolizers and have an elimination half-life of 15 to 20 hours for the parent compound and almost no 5-hydroxypropafenone. The (+)-enantiomer provides nonspecific beta-adrenergic receptor blockade with 2.5% to 5% of the potency of propranolol, but because plasma propafenone concentrations may be 50 or more times higher than propranolol levels, these beta-blocking properties may be relevant. Poor metabolizers have a greater beta-adrenergic receptor-blocking effect than extensive metabolizers do.

DOSAGE AND ADMINISTRATION. Most patients respond to oral doses of 150 to 300 mg every 8 hours, not to exceed 1200 mg/day (see Table 35-4). Doses are similar for patients of both metabolizing phenotypes. A sustained-release form is available for the treatment of atrial fibrillation; dosing is 225 to 425 mg twice daily. Concomitant food administration increases its bioavailability, as does hepatic dysfunction. No good correlation between the plasma propafenone concentration and suppression of arrhythmia has been shown. Doses should not be increased more often than every 3 to 4 days. Propafenone increases plasma concentrations of warfarin, digoxin, and metoprolol.

INDICATIONS. Propafenone is indicated for the treatment of paroxysmal SVT, atrial fibrillation, and life-threatening ventricular tachyarrhythmias and effectively suppresses spontaneous PVCs and nonsustained and sustained VT.⁷ Acute termination of atrial fibrillation episodes occurred with a single 600-mg oral dose of propafenone in 76% of patients given the drug (twice the rate of those given placebo). It has been used effectively in the pediatric age group. Propafenone increases the pacing threshold but minimally affects the defibrillation threshold. The sinus rate during exercise is reduced.

ADVERSE EFFECTS. Minor noncardiac effects occur in approximately 15% of patients, with dizziness, disturbances in taste, and blurred vision being the most common and gastrointestinal side effects next. Exacerbation of bronchospastic lung disease can occur because of mild beta-blocking effects. Cardiovascular side effects develop in 10% to 15% of patients, including AV block, sinus node depression, and worsening of heart failure. Proarrhythmic responses, which occur more often in patients with a history of sustained VT and decreased ejection fractions, appear less commonly than with flecainide (~5%). Applicability of data from CAST about flecainide to propafenone is not clear, but limiting the application of propafenone in a manner similar to that of other class IC drugs seems prudent. Its beta-blocking actions may make it different, however. The safety of propafenone administration during pregnancy has not been established (class C).

Moricizine

As of December 31, 2007, moricizine (Ethmazine) is no longer available in the United States.

Class II Agents

Beta Adrenoceptor-Blocking Agents

Although many beta adrenoceptor-blocking drugs have been approved for use in the United States, metoprolol, carvedilol, atenolol, propranolol, and esmolol have been most widely used to treat supraventricular and ventricular arrhythmias. Acebutolol, nadolol, timolol, betaxolol, pindolol, and bisoprolol have been used less extensively for the treatment of arrhythmias. Metoprolol, atenolol, carvedilol, timolol, and propranolol decrease overall mortality and sudden death after myocardial infarction (see Chapter 39). It is generally thought that beta blockers possess class effects and that when titrated to the proper dose, all can be used effectively to treat cardiac arrhythmias, hypertension, or other disorders. However, differences in pharmacokinetic or pharmacodynamic properties that confer safety, reduce adverse effects, or affect dosing intervals or drug interactions influence the choice of agent. For example, nadolol may be particularly effective in patients with long-QT syndrome (see Chapter 32). Also, some beta blockers, such as sotalol, pindolol, and carvedilol, exert unique actions in addition to beta receptor blockade.

Beta receptors can be separated into those that affect predominantly the heart (beta₁) and those that affect predominantly blood vessels and the bronchi (beta₂). In low doses, selective beta blockers can block beta₁ receptors more than they block beta₂ receptors and

might be preferable for the treatment of patients with pulmonary or peripheral vascular disease. In high doses, the “selective” β_1 blockers also block β_2 receptors. Carvedilol also exerts α -blocking effects and is used primarily in patients with heart failure (see [Chapters 23 to 25](#)). It is not an ideal agent for rate control in atrial fibrillation because of the α -blocking–induced hypotension that accompanies doses large enough to block the AV node.

Some beta blockers exert intrinsic sympathomimetic activity; that is, they slightly activate the beta receptor. These drugs appear to be as efficacious as beta blockers without intrinsic sympathomimetic actions and may cause less slowing of the heart rate at rest and less prolongation of AV nodal conduction time. They have been shown to induce less depression of left ventricular function than do beta blockers without intrinsic sympathomimetic activity. Beta blockers without intrinsic sympathomimetic activity have been shown to reduce mortality in patients after myocardial infarction, with nonselective agents possibly conferring slightly greater benefit (see [Chapters 51 and 52](#)).

The following discussion focuses on the use of propranolol as a prototypic antiarrhythmic agent but is generally applicable to other beta blockers.

Electrophysiologic Actions. Beta blockers exert an electrophysiologic action by competitively inhibiting binding of catecholamine at beta adrenoceptor sites, an effect almost entirely the result of the (–)-levorotatory stereoisomer, or by their quinidine-like or direct membrane-stabilizing action (see [Tables 35-1, 35-2, 35-3, and 35-5](#)). The latter is a local anesthetic effect that depresses I_{Na} and membrane responsiveness in cardiac Purkinje fibers, occurs at concentrations generally 10 times those necessary to produce beta blockade, and most likely plays an insignificant antiarrhythmic role. Thus, beta blockers exert their major effects in cells most actively stimulated by adrenergic actions. At a beta-blocking concentration, propranolol slows spontaneous automaticity in the sinus node or in Purkinje fibers that are being stimulated by adrenergic tone and produces an I_f block (see [Chapter 33](#)). Beta blockers also block the $I_{Ca,L}$ stimulated by beta agonists. In the absence of adrenergic stimulation, only high concentrations of propranolol slow normal automaticity in Purkinje fibers, probably by a direct membrane action.

Concentrations that cause beta receptor blockade but no local anesthetic effects do not alter the normal resting membrane potential, maximum diastolic potential amplitude, V_{max} , repolarization, or refractoriness of atrial, Purkinje, or ventricular muscle cells in the absence of catecholamine stimulation. However, in the presence of isoproterenol, a relatively pure beta receptor stimulator, beta blockers reverse isoproterenol's accelerating effects on repolarization. Propranolol reduces the amplitude of digitalis-induced delayed afterdepolarizations and suppresses triggered activity in Purkinje fibers.

Concentrations exceeding 3 mg/mL are required to depress V_{max} , action potential amplitude, membrane responsiveness, and conduction in normal atrial, ventricular, and Purkinje fibers without altering resting membrane potential. These effects probably result from depression of I_{Na} . Long-term administration of propranolol may lengthen the APD. Similar to the effects of lidocaine, acceleration of repolarization of Purkinje fibers is most marked in areas of the ventricular conduction system in which the APD is greatest.

Propranolol slows the sinus discharge rate in humans by 10% to 20%, although severe bradycardia occasionally results if the heart is particularly dependent on sympathetic tone or if sinus node dysfunction is present. The PR interval lengthens, as do AV nodal conduction time and AV nodal effective and functional refractory periods (at a constant heart rate), but refractoriness and conduction in the normal His-Purkinje system remain unchanged, even after high doses of propranolol. Therefore, therapeutic doses of propranolol in humans do not exert a direct depressant or “quinidine-like” action but influence cardiac electrophysiology through a beta-blocking action. Beta blockers do not affect conduction or repolarization in normal ventricular muscle, as evidenced by their lack of effect on the QRS complex and QT interval, respectively.

Because administration of beta blockers that do not have direct membrane action prevents many arrhythmias resulting from activation of the autonomic nervous system, it is thought that the beta-blocking action is responsible for their antiarrhythmic effects. Nevertheless, the possible importance of the direct membrane effect of some of these drugs cannot be discounted totally because beta blockers with direct membrane actions can affect the transmembrane potentials of

diseased cardiac fibers at much lower concentrations than are needed to affect normal fibers directly. However, indirect actions on the arrhythmogenic effects of ischemia are probably the most important.

Hemodynamic Effects. Beta blockers exert negative inotropic effects and can precipitate or worsen heart failure. However, beta blockers clearly improve survival in patients with heart failure (see [Chapter 25](#)). By blocking beta receptors, these drugs may allow unopposed α -adrenergic effects to produce peripheral vasoconstriction and exacerbate coronary artery spasm or pain from peripheral vascular disease in some patients.

Pharmacokinetics. Although various types of beta blockers exert similar pharmacologic effects, their pharmacokinetics differs substantially. Propranolol is almost 100% absorbed, but the effects of first-pass hepatic metabolism reduce its bioavailability to approximately 30% and produce significant interpatient variability in plasma concentration with a given dose (see [Table 35-4](#)). Reduced hepatic blood flow, as in patients with heart failure, decreases the hepatic extraction of propranolol; in these patients, propranolol may further decrease its own elimination rate by reducing cardiac output and hepatic blood flow. Beta blockers eliminated by the kidneys tend to have longer half-lives and exhibit less interpatient variability in drug concentration than do beta blockers metabolized by the liver.

DOSAGE AND ADMINISTRATION. The appropriate dose of propranolol is best determined by a measure of the patient's physiologic response, such as changes in resting heart rate or prevention of exercise-induced sinus tachycardia, because wide individual differences exist between the observed physiologic effect and plasma concentration. For example, intravenous dosing is best achieved by titration of the dose to clinical effect, beginning with doses of 0.25 to 0.50 mg, increasing to 1.0 mg if necessary, and administering doses every 5 minutes until either a desired effect or toxicity is produced or a total of 0.15 to 0.20 mg/kg has been given. In many cases, the short-acting effects of esmolol are preferred. Orally, propranolol is given in four divided doses, usually ranging from 40 to 160 mg/day to more than 1 g/day (see [Table 35-4](#)). Some beta blockers, such as carvedilol and pindolol, need to be given twice daily; many are available as once-daily long-acting preparations. In general, if one agent in adequate doses does not produce the desired effect, other beta blockers will also be ineffective. Conversely, if one agent produces the desired physiologic effect but a side effect develops, another beta blocker can often be substituted successfully.

INDICATIONS. Arrhythmias associated with thyrotoxicosis or pheochromocytoma and arrhythmias largely related to excessive cardiac adrenergic stimulation, such as those initiated by exercise, emotion, or cocaine, often respond to beta blocker therapy. Beta-blocking drugs do not usually convert chronic atrial flutter or atrial fibrillation to normal sinus rhythm but may do so if the arrhythmia is of recent onset and in patients who have recently undergone cardiac surgery. The atrial rate during atrial flutter or fibrillation is not changed, but the ventricular response decreases because beta blockade prolongs AV nodal conduction time and refractoriness. Esmolol can be used intravenously for rapid control of the heart rate. For reentrant SVTs using the AV node as one of the reentrant pathways, such as AV nodal reentrant tachycardia (AVNRT) and orthodromic reciprocating tachycardia in Wolff-Parkinson-White syndrome or inappropriate sinus tachycardia, or for AT, beta blockers can slow or terminate the tachycardia and can be used prophylactically to prevent a recurrence. Combining beta blockers with digitalis, quinidine, or various other agents can be effective when the beta blocker as a single agent fails. Metoprolol and esmolol may be useful in patients with multifocal AT. These agents must be used with caution in patients with this arrhythmia, however, because a common setting for it is advanced lung disease, often with a bronchospastic component.

Beta blockers can be effective for digitalis-induced arrhythmias such as AT, nonparoxysmal AV junctional tachycardia, PVCs, or VT. If a significant degree of AV block is present during digitalis-induced arrhythmia, lidocaine or phenytoin may be preferable to propranolol. Beta blockers can also be useful to treat ventricular arrhythmias associated with prolonged-QT interval syndrome (see [Chapter 32](#)) and with mitral valve prolapse (see [Chapter 63](#)). For patients with

ischemic heart disease, beta blockers do not generally prevent the episodes of recurrent monomorphic VT that occur in the absence of acute ischemia. It is well accepted that several beta blockers reduce the incidence of both total and sudden death after myocardial infarction (see Chapters 51 and 52). The mechanism of this reduction in mortality is not entirely clear and may be related to reduction of the extent of ischemic damage, autonomic effects, a direct antiarrhythmic effect, or combinations of these factors. Beta blockers may have been protective against proarrhythmic responses in CAST.

ADVERSE EFFECTS. Adverse cardiovascular effects from beta blockers include unacceptable hypotension, bradycardia, and congestive heart failure. The bradycardia can be caused by sinus slowing or AV block. Sudden withdrawal of propranolol in patients with angina pectoris can precipitate or worsen angina and cardiac arrhythmias and cause acute myocardial infarction, possibly as a result of the heightened sensitivity to beta agonists caused by previous beta blockade (receptor upregulation). Heightened sensitivity may begin several days after cessation of beta blocker therapy and can last 5 or 6 days. Other adverse effects of beta blockers include worsening of asthma or chronic obstructive pulmonary disease, intermittent claudication, Raynaud phenomenon, mental depression, increased risk for hypoglycemia in insulin-dependent diabetic patients, easy fatigability, disturbingly vivid dreams or insomnia, and impaired sexual function. Many of these side effects were noted less frequently with the use of beta₁-selective agents, but even so-called cardioselective beta blockers can exacerbate asthma or diabetic control in individual patients.

Class III Agents

Amiodarone

Amiodarone is a benzofuran derivative approved by the FDA for the treatment of patients with life-threatening ventricular tachyarrhythmias when other drugs are ineffective or not tolerated. Dronedarone, a noniodinated derivative of amiodarone, is approved by the FDA for the treatment of atrial fibrillation (see later).

Electrophysiologic Actions. When it is chronically given orally, amiodarone prolongs the APD and refractoriness of all cardiac fibers without affecting resting membrane potential (see Tables 35-1, 35-2, 35-3, and 35-5 and Chapter 33). When acute effects are evaluated, amiodarone and its metabolite desethylamiodarone prolong the APD of ventricular muscle but shorten the APD of Purkinje fibers. Injected into the sinus and AV node arteries, amiodarone reduces sinus and junctional discharge rates and prolongs AV nodal conduction time. It depresses \dot{V}_{\max} in ventricular muscle in a rate- or use-dependent manner by blocking of inactivated sodium channels, an effect that is accentuated by depolarized and reduced by hyperpolarized membrane potentials. Amiodarone depresses conduction at fast rates more than at slow rates (use dependence), not only by depressing \dot{V}_{\max} but also by increasing resistance to passive current flow. It does not prolong repolarization more at slow than at fast rates (i.e., does not demonstrate reverse use dependence) but does exert time-dependent effects on refractoriness, which may in part explain its high antiarrhythmic efficacy and low incidence of torsades de pointes.

Desethylamiodarone has relatively greater effects on fast-channel tissue, which probably contributes notably to its antiarrhythmic efficacy. The delay in building up adequate concentrations of this metabolite may in part explain the delay in amiodarone's antiarrhythmic action.

Amiodarone noncompetitively antagonizes alpha and beta receptors and blocks conversion of thyroxine (T_4) to triiodothyronine (T_3), which may account for some of its electrophysiologic effects. Amiodarone exhibits slow-channel-blocking effects; with oral administration, it slows the sinus rate by 20% to 30% and prolongs the QT interval, at times changing the contour of the T wave and producing U waves.

The ERP of all cardiac tissues is prolonged. The H-V interval increases and the QRS duration lengthens, especially at fast rates. Amiodarone given intravenously modestly prolongs the refractory period of atrial and ventricular muscle. The PR interval and AV nodal conduction time lengthen. The duration of the QRS complex lengthens at increased rates but less than after oral amiodarone. Thus, a far less increase in prolongation of conduction time (except for the AV node), duration of repolarization, and refractoriness occurs after intravenous

administration than after the oral route. Considering these actions, it is clear that amiodarone has class I (blocks I_{Na}), class II (antiadrenergic), and class IV (blocks I_{CaL}) actions in addition to its class III effects (blocks I_K). Amiodarone's actions approximate those of a theoretically ideal drug that exhibits use-dependent Na^+ channel blockade with fast diastolic recovery from block and use-dependent prolongation of the APD. It does not increase and may decrease QT dispersion. Catecholamines can partially reverse some of the effects of amiodarone.

Hemodynamic Effects. Amiodarone is a peripheral and coronary vasodilator. When administered intravenously (150 mg over a 10-minute period, then a 1-mg/min infusion), amiodarone decreases the heart rate, systemic vascular resistance, left ventricular contractile force, and left ventricular dP/dt. Oral doses of amiodarone sufficient to control cardiac arrhythmias do not depress the left ventricular ejection fraction, even in patients with reduced ejection fractions, and the ejection fraction and cardiac output may increase slightly. However, because of the antiadrenergic actions of amiodarone and because it does exert some negative inotropic action, it should be given cautiously, particularly intravenously, to patients with marginal cardiac compensation.

Pharmacokinetics. Amiodarone is slowly, variably, and incompletely absorbed, with a systemic bioavailability of 35% to 65% (see Table 35-4). Plasma concentrations peak 3 to 7 hours after a single oral dose. There is a minimal first-pass effect, thus indicating little hepatic extraction. Elimination is by hepatic excretion into bile with some enterohepatic recirculation. Extensive hepatic metabolism occurs, with desethylamiodarone being a major metabolite. Both accumulate extensively in the liver, lung, fat, "blue" skin, and other tissues. The concentration in myocardium is 10 to 50 times that found in plasma. Plasma clearance of amiodarone is low, and renal excretion is negligible. Doses need not be reduced in patients with renal disease. Amiodarone and desethylamiodarone are not dialyzable. The volume of distribution is large but variable, with an average of 60 L/kg. Amiodarone is highly protein bound (96%), crosses the placenta (10% to 50%), and is found in breast milk.

The onset of action after intravenous administration generally occurs within 1 to 2 hours. After oral administration, the onset of action may require 2 to 3 days, often 1 to 3 weeks, and on occasion even longer. Loading doses reduce this time interval. Plasma concentrations relate well to oral doses during chronic treatment and average approximately 0.5 mg/mL for each 100 mg/day at doses between 100 and 600 mg/day. Its elimination half-life is multiphasic, with an initial 50% reduction in plasma concentration 3 to 10 days after cessation of drug ingestion (probably representing elimination from well-perfused tissues), followed by a terminal half-life of 26 to 107 days (mean, 53 days), with most patients being in the 40- to 55-day range. To achieve a steady-state concentration without a loading dose takes about 265 days. Interpatient variability in these pharmacokinetic parameters mandates close monitoring of the patient. Therapeutic serum concentrations range from 1 to 2.5 mg/mL. Greater suppression of arrhythmias may occur with up to 3.5 mg/mL, but the risk for side effects increases.

DOSAGE AND ADMINISTRATION. An optimal dosing schedule for all patients has not been achieved. One recommended approach is to treat with 800 to 1200 mg/day for 1 to 3 weeks, 400 mg/day for the next several weeks, and finally after 2 to 3 months of treatment, a maintenance dose of 300 mg or less per day (see Table 35-4). Maintenance drug can be given once or twice daily and should be titrated to the lowest effective dose to minimize the occurrence of side effects; in general, the earlier during drug loading that arrhythmia control is achieved, the lower the maintenance dose can be. Doses as low as 100 mg/day can be effective in some patients. Regimens must be individualized for a given patient and clinical situation. To achieve more rapid loading and effect in emergencies, amiodarone can be administered intravenously at initial doses of 15 mg/min for 10 minutes, followed by 1 mg/min for 6 hours and then 0.5 mg/min for the remaining 18 hours and the next several days as necessary. Supplemental infusions of 150 mg over a 10-minute period can be used for breakthrough VT or VF. Intravenous infusions can be continued safely for 2 to 3 weeks. Intravenous amiodarone is generally well tolerated, even in patients with left ventricular dysfunction. Patients with depressed ejection fractions should receive intravenous amiodarone with great caution because of hypotension. High-dose oral loading (800 to 2000 mg/day to maintain trough serum

concentrations of 2 to 3 mg/mL) may suppress ventricular arrhythmias in 1 to 2 days.

INDICATIONS. Amiodarone has been used to suppress a wide spectrum of supraventricular and ventricular tachyarrhythmias in utero, in adults, and in children, including AV node and AV reentry junctional tachycardia, atrial flutter and fibrillation, VT and VF associated with coronary artery disease, and hypertrophic cardiomyopathy. Success rates vary widely, depending on the population of patients, arrhythmia, underlying heart disease, length of follow-up, definition and determination of success, and other factors. In general, however, the efficacy of amiodarone equals or exceeds that of all other antiarrhythmic agents and may be in the range of 60% to 80% for most supraventricular tachyarrhythmias and 40% to 60% for ventricular tachyarrhythmias. Amiodarone may be useful in improving survival in patients with hypertrophic cardiomyopathy, asymptomatic ventricular arrhythmias after myocardial infarction, and ventricular tachyarrhythmia during and after resuscitation from cardiac arrest. Amiodarone given before open heart surgery, as well as postoperatively, has been shown to decrease the incidence of postoperative atrial fibrillation. Amiodarone is superior to class I antiarrhythmic agents and sotalol in maintaining sinus rhythm in patients with recurrent atrial fibrillation.

Patients who have an ICD receive fewer shocks if they are treated with amiodarone than if treated with conventional drugs. Amiodarone has little effect on the pacing threshold but typically increases the electrical defibrillation threshold slightly.

Several prospective, randomized, controlled trials and meta-analyses have demonstrated improved survival with amiodarone therapy versus placebo; however, amiodarone has been proved to result in inferior survival in comparison to ICD therapy, and in the SCD-HeFT population (Class II or III heart failure; ejection fraction, 35%), survival of amiodarone-treated patients was no different from that of those treated with placebo. The drug may still be used adjunctively in ICD-treated patients to decrease the frequency of shocks from VT and VF episodes or to control supraventricular tachyarrhythmias that elicit device therapy (see Chapter 37). The drug can slow the ventricular rate during spontaneous VT episodes beneath the detection rate of the device; careful patient assessment and, occasionally, device reprogramming and testing are necessary. It also can be used to slow the ventricular rate during atrial fibrillation and atrial flutter.

Because of the serious nature of the arrhythmias being treated, the unusual pharmacokinetics of the drug, and its adverse effects, consideration should be given to starting amiodarone therapy with the patient hospitalized and monitored for at least several days. Combining other antiarrhythmic agents with amiodarone may improve efficacy in some patients.

ADVERSE EFFECTS. Adverse effects are reported by about 75% of patients treated with amiodarone for 5 years, and these effects compel stopping use of the drug in 18% to 37%. The most frequent side effects requiring drug discontinuation involve pulmonary and gastrointestinal complaints or abnormal test results. Most adverse effects are reversible with dose reduction or cessation of treatment. Adverse effects are more common when therapy is continued in the long term and at higher doses. Of the noncardiac adverse reactions, pulmonary toxicity is the most serious⁸; in one study it occurred in 33 of 573 patients between 6 days and 60 months of treatment, with three deaths. The mechanism is unclear but may involve a hypersensitivity reaction, widespread phospholipidosis, or both. Dyspnea, nonproductive cough, and fever are common symptoms, along with crackles on examination, hypoxia, abnormal gallium scan results, reduced diffusion capacity, and radiographic evidence of pulmonary infiltrates. Amiodarone must be discontinued if such pulmonary inflammatory changes occur. Corticosteroids can be tried, but no controlled studies have been done to support their use. Ten percent mortality results in patients with pulmonary inflammatory changes, often in those with unrecognized pulmonary involvement that is allowed to progress. Chest radiography and pulmonary function testing, including carbon monoxide diffusion capacity (DLCO), at 3-month intervals for the first year and then twice a year for several

years have been recommended. At maintenance doses lower than 300 mg/day, pulmonary toxicity is uncommon but can occur. Advanced age, high drug maintenance dose, and reduced predrug diffusion capacity are risk factors for the development of pulmonary toxicity. An unchanged DLCO on therapy may be a negative predictor of pulmonary toxicity.

Although asymptomatic elevations in liver enzyme levels are found in most patients, the drug is not stopped unless values exceed two or three times normal in a patient with initially normal values. Cirrhosis occurs uncommonly but may be fatal.⁹ Neurologic dysfunction, photosensitivity (perhaps minimized by sunscreens), bluish skin discoloration, gastroenterologic disturbances, and hyperthyroidism (1% to 2%) or hypothyroidism (2% to 4%) can occur.¹⁰ Because amiodarone appears to inhibit the peripheral conversion of T_4 to T_3 , chemical changes result and are characterized by a slight increase in T_4 , reverse T_3 , and thyroid-stimulating hormone (TSH) and a slight decrease in T_3 levels. The reverse T_3 concentration has been used as an index of drug efficacy. During hypothyroidism the TSH level increases greatly, whereas the level of T_3 increases in hyperthyroidism. Thyroid function tests should be performed approximately every 3 months for the first year while amiodarone is being taken and once or twice yearly thereafter, sooner if symptoms develop that are consistent with thyroid dysfunction. Corneal microdeposits occur in almost 100% of adults receiving the drug longer than 6 months. More serious ocular reactions, including optic neuritis and atrophy with visual loss, have been reported but are rare, and causation by amiodarone has not been established.

Cardiac side effects include symptomatic bradycardias in approximately 2% of patients; worsening of ventricular tachyarrhythmias with the occasional development of torsades de pointes in 1% to 2%, possibly higher in women; and worsening of congestive heart failure in 2%. Possibly because of interactions with anesthetics, complications after open heart surgery, including pulmonary dysfunction, hypotension, severe bradycardia, hepatic dysfunction, and low cardiac output, have been noted by some investigators.

In general, the lowest possible maintenance dose of amiodarone that is still effective should be used to avoid significant adverse effects. Many supraventricular arrhythmias can be managed successfully with daily dosages of 200 mg or less, whereas ventricular arrhythmias generally require higher doses. Adverse effects are uncommon at dosages of 200 mg/day or less but still occur. Because of potential toxicity in various organ systems, special multidisciplinary amiodarone clinics have been used by some in an attempt to prevent adverse outcomes when the drug is used.

Important interactions with other drugs occur, and when given concomitantly with amiodarone, the doses of warfarin, digoxin, and other antiarrhythmic drugs should be reduced by a third to a half and the patient observed closely. Drugs with synergistic actions, such as beta blockers or calcium channel blockers, must be given cautiously. The safety of amiodarone during pregnancy has not been established, and it should be used in pregnant patients only if no alternatives exist.

Dronedarone

Dronedarone is approved by the FDA to facilitate maintenance of sinus rhythm in patients with atrial flutter and fibrillation.

Electrophysiologic Actions. Like amiodarone, dronedarone alters the activity of multiple cardiac ion channels (see Tables 35-1, 35-2, 35-3, and 35-5). It is a more potent blocker of the rapid sodium current than amiodarone is and exhibits similar effects on the L-type calcium current. Blockade of both the rapid and slow components of the delayed rectifier potassium current by dronedarone is also similar to that by amiodarone, whereas its effect on the atrial acetylcholine-activated potassium current and antiadrenergic effects (via noncompetitive binding) are significantly more potent than that of amiodarone. Sinus node function is depressed to a minor degree. Pacing and defibrillation thresholds are slightly increased.

Hemodynamic Effects. Dronedarone has little effect on cardiac performance except in patients with compromised ventricular systolic function and should not be used in those with clinical signs of heart failure.

Pharmacokinetics. Dronedaronе is 70% to 90% absorbed after oral administration, with peak plasma concentrations being achieved in 3 to 4 hours; absorption is enhanced by food (see Table 35-4). Unlike the very long half-life of amiodarone, the elimination half-life of dronedaronе is 13 to 19 hours, with 85% of the drug being excreted unchanged in feces and the remainder in urine. Dronedaronе is metabolized by and slightly inhibits the activity of CYP3A4 (as well as CYP2D6) and should not be used in conjunction with other agents that strongly inhibit these enzyme systems. There is little warfarin interaction, but dronedaronе increases serum levels of dabigatran.

DOSAGE AND ADMINISTRATION. The standard recommended dose is 400 mg every 12 hours with food (see Table 35-4). No parenteral form is currently available.

INDICATIONS. Dronedaronе is indicated to facilitate cardioversion of atrial flutter or fibrillation or to maintain sinus rhythm after restoration of sinus rhythm. It is slightly less effective than amiodarone in these regards.¹¹ In the ANDROMEDA (Antiarrhythmic Trial with Dronedaronе in Moderate-to-Severe Congestive Heart Failure Evaluating Morbidity Decrease) study, dronedaronе-treated patients had a mortality rate more than twice that of placebo (8.1% versus 3.8%). Similarly, in the PALLAS (Permanent Atrial Fibrillation Outcome Study Using Dronedaronе on Top of Standard Therapy) trial, patients with permanent atrial fibrillation who were taking dronedaronе had a greater than twofold higher risk for death, stroke, systemic embolism, or myocardial infarction than did control patients.¹² Thus, the medication should not be used in patients with current or recent episodes of clinical heart failure or in those with permanent atrial fibrillation (as a rate control agent). Patients taking dronedaronе should be evaluated periodically to ensure that permanent fibrillation or heart failure has not developed.

ADVERSE EFFECTS. A transient, predictable increase in serum creatinine, without adversely affecting actual glomerular filtration or other measures of renal function, occurs with standard dosing and is not a reason to alter the dose or to discontinue use of the drug. As noted, patients with New York Heart Association class III or IV heart failure, as well as those with permanent atrial fibrillation, should not be given the drug because these patients have higher mortality. Patients with severe liver dysfunction should not generally receive the drug. The QT interval is predictably prolonged, but proarrhythmic effects from this or other mechanisms are rare (although sinus bradycardia is sometimes seen). Rash, photosensitivity, nausea, diarrhea, dyspepsia, headache, and asthenia have occurred in treated patients at higher frequency than in controls. Absence of the iodine molecule appears to account for the lower prevalence of lung and thyroid toxicity in dronedaronе-treated patients than in those taking amiodarone. Dronedaronе should not be used during pregnancy (category X, evidence or risk of fetal harm) and is possibly unsafe for breast feeding.

Bretylum Tosylate

Bretylum is a quaternary ammonium compound that had been used parenterally in patients with life-threatening ventricular tachyarrhythmias. Because of poor efficacy, it is no longer manufactured or available in the United States.

Sotalol

Sotalol is a nonspecific beta adrenoceptor blocker without intrinsic sympathomimetic activity that prolongs repolarization. It is approved by the FDA to treat patients with life-threatening ventricular tachyarrhythmias and those with atrial fibrillation.

Electrophysiologic Actions. Both the *d*- and *l*-isomers have similar effects on prolonging repolarization, whereas the *l*-isomer is responsible for almost all the beta-blocking activity (see Tables 35-1, 35-2, 35-3, and 35-5). Sotalol does not block alpha adrenoceptors and does not block the sodium channel (no membrane-stabilizing effects) but does prolong atrial and ventricular repolarization times by reducing I_{Kr} , thus prolonging the plateau of the action potential. Action potential prolongation is greater at slower rates (reverse use dependence). Resting membrane potential, action potential amplitude, and V_{max} are not significantly altered. Sotalol prolongs atrial and ventricular refractoriness, A-H and QT intervals, and sinus cycle length (see Chapter 37).

Hemodynamics. Sotalol exerts a negative inotropic effect only through its beta-blocking action. Although it can increase the strength of contraction by prolonging repolarization, which occurs maximally at slow heart rates, the negative inotropic effects predominate. In patients with reduced cardiac function, sotalol can decrease the cardiac index, increase filling pressure, and precipitate overt heart failure. Therefore, it must be used cautiously in patients with marginal cardiac compensation but is well tolerated in those with normal cardiac function.

Pharmacokinetics. Sotalol is completely absorbed and not metabolized, thus making it 90% to 100% bioavailable. It is not bound to plasma proteins, is excreted unchanged primarily by the kidneys, and has an elimination half-life of 10 to 15 hours (see Table 35-4). Peak plasma concentrations occur 2.5 to 4 hours after oral ingestion. Over the dose range of 160 to 640 mg, sotalol displays dose proportionality with plasma concentration (usually in the range of 2.5 $\mu\text{g/mL}$). The dose must be reduced in patients with renal disease. The beta-blocking effect is half-maximal at 80 mg/day and maximal at 320 mg/day.

DOSAGE. The typical oral dose is 80 to 160 mg every 12 hours, with 2 to 3 days being allowed between dose adjustments to attain a steady-state concentration and to monitor the ECG for arrhythmias and QT prolongation (see Table 35-4). Doses exceeding 320 mg/day can be used in patients when the potential benefits outweigh the risk for proarrhythmia. Because of its ability to significantly prolong the QT interval in some patients and cause torsades de pointes or provoke severe bradycardia, consideration should be given to inpatient initiation of the drug, especially in those with atrial fibrillation (in whom conversion to sinus bradycardia may cause syncope and/or further QT prolongation at slow rates), as well as in women (with longer baseline QT intervals).

INDICATIONS. Approved by the FDA to treat patients with ventricular tachyarrhythmias and atrial fibrillation, sotalol is also useful to prevent recurrence of a wide variety of SVTs, including atrial flutter, AT, AV node reentry, and AV reentry (see Chapter 37). It also slows the ventricular response to atrial tachyarrhythmias. It appears to be more effective than conventional antiarrhythmic drugs and may be comparable to amiodarone in the treatment of patients with ventricular tachyarrhythmias, as well as in prevention of recurrences of atrial fibrillation after cardioversion. It has been used successfully to decrease the incidence of atrial fibrillation after cardiac surgery.¹³ Sotalol may be effective in fetal and pediatric patients and young adults with congenital heart disease.¹⁴ Unlike most other antiarrhythmic drugs, it may decrease the frequency of ICD discharges and reduce the defibrillation threshold.

ADVERSE EFFECTS. Proarrhythmia is the most serious adverse effect. Overall, new or worsened ventricular tachyarrhythmias occur in approximately 4% of patients; this response is the result of torsades de pointes in around 2.5% but increases to 4% in patients with a history of sustained VT and is dose related (only 1.6% at 320 mg/day but 4.4% at 480 mg/day). This proarrhythmic effect was probably the cause of excess mortality in patients given *d*-sotalol (the enantiomer lacking a beta-blocking effect) after acute myocardial infarction in the SWORD (Survival With Oral *d*-Sotalol) trial. Other adverse effects commonly seen with other beta blockers also apply to sotalol. Sotalol should be used with caution or not at all in combination with other drugs that prolong the QT interval. However, such combinations have occasionally been used successfully.

Ibutilide

Ibutilide is an agent released for acute termination of episodes of atrial flutter and fibrillation (see Chapter 37).

Electrophysiologic Actions. Like other class III agents, ibutilide prolongs repolarization (see Tables 35-1, 35-2, 35-3, and 35-5). Although it is similar to other class III agents that block outward potassium currents, such as I_{Kr} , ibutilide is unique in that it also activates a slow inward sodium current. Administered intravenously, ibutilide causes mild slowing of the sinus rate and has minimal effects on AV conduction or QRS duration, but the QT interval is characteristically prolonged. Ibutilide has no significant effect on hemodynamics.

Pharmacokinetics. Ibutilide is administered intravenously and has a large volume of distribution (see Table 35-4). Clearance is

predominantly renal, with a drug half-life averaging 6 hours, but with considerable interpatient variability. Protein binding is approximately 40%. One of the drug's metabolites has weak class III effects.

DOSAGE AND ADMINISTRATION. Ibutilide is given as an intravenous infusion of 1 mg over a 10-minute period (see Table 35-4). It should not be given in the presence of a QTc interval longer than 440 milliseconds or other drugs that prolong the QT interval or in patients with uncorrected hypokalemia, hypomagnesemia, or bradycardia. A second 1-mg dose may be given after the first dose is finished if the arrhythmia persists. Patients must have continuous electrocardiographic monitoring throughout the dosing period and for 6 to 8 hours thereafter because of the risk for ventricular arrhythmias. Pretreatment with intravenous magnesium may decrease the risk for ventricular arrhythmias and enhance efficacy in treating some atrial arrhythmias.¹⁵ Up to 60% of patients with atrial fibrillation and 70% of those with atrial flutter convert to sinus rhythm after 2 mg of ibutilide has been administered.

INDICATIONS. Ibutilide is indicated for termination of an established episode of atrial flutter or fibrillation. It should not be used in patients with frequent short paroxysms of atrial fibrillation because it merely terminates episodes and is not useful for long-term prevention. Patients whose condition is hemodynamically unstable should proceed to direct-current cardioversion. Ibutilide has been used safely and effectively in patients who were already taking amiodarone or propafenone but should be used with caution in these cases. Ibutilide has been administered at the time of transthoracic electrical cardioversion to increase the likelihood of termination of atrial fibrillation. In one study, all 50 patients given ibutilide before attempted electrical cardioversion achieved sinus rhythm, whereas only 34 of 50 who did not receive the drug converted to sinus rhythm. Of note, all 16 patients who did not respond to electrical cardioversion without ibutilide were successfully electrically cardioverted to sinus rhythm when a second attempt was made after ibutilide pretreatment.

Ibutilide prolongs accessory pathway refractoriness and can temporarily slow the ventricular rate during preexcited atrial fibrillation. The drug can also occasionally terminate episodes of organized AT, as well as sustained, uniform-morphology VT.

ADVERSE EFFECTS. The most significant adverse effect of ibutilide is QT prolongation–related torsades de pointes, which occurs in approximately 2% of patients given the drug (twice as often in women as in men). This effect develops within the first 4 to 6 hours of dosing, after which the risk is negligible. Thus, patients in whom the drug is used must undergo electrocardiographic monitoring for up to 8 hours after dosing. This requirement can make the use of ibutilide in emergency departments or private offices problematic. The safety of ibutilide during pregnancy has not been well studied, and its use in this setting should be restricted to patients in whom no safer alternative exists.

Dofetilide

Dofetilide is approved for the acute conversion of atrial fibrillation to sinus rhythm, as well as for chronic suppression of recurrent atrial fibrillation.¹⁶

Electrophysiologic Actions. The sole electrophysiologic effect of dofetilide is block of the rapid component of the delayed rectifier potassium current (I_{Kr}), important in repolarization (see Tables 35-1, 35-2, 35-3, and 35-5). This effect is more prominent in the atria than in the ventricles—30% increase in the atrial refractory period versus 20% in the ventricle. The effect of dofetilide on I_{Kr} is prolongation of refractoriness without slowing conduction, which is believed to be largely responsible for its antiarrhythmic effect. It is also responsible for prolongation of the QT interval on the ECG, which averages 11% but can be much greater. This effect on the QT interval is dose dependent and linear. No other important electrocardiographic changes are observed with the drug. It has no significant hemodynamic effects. Dofetilide is more effective than quinidine at converting atrial fibrillation to sinus rhythm. Its long-term efficacy is similar to that of other agents.¹⁷

Pharmacokinetics. Orally administered dofetilide is absorbed well, and more than 90% is bioavailable. Its mean elimination half-life is 7 to 13 hours, with 50% to 60% of the drug being excreted unchanged

in urine (see Table 35-4). The remainder of the drug undergoes hepatic metabolism to inert compounds. Significant drug-drug interactions have been reported in patients taking dofetilide; cimetidine, verapamil, ketoconazole, and trimethoprim, alone or in combination with sulfamethoxazole, cause a significant elevation in the dofetilide serum concentration and should not be used with this drug.

DOSAGE AND ADMINISTRATION. Dofetilide is available only as an oral preparation. Dosing is from 0.125 to 0.5 mg twice daily and must be initiated in a hospital setting with continuous electrocardiographic monitoring to ensure that inordinate QT prolongation and torsades de pointes do not develop (see Table 35-4). Physicians must be specially certified to prescribe the drug. Its dosage must be decreased in the presence of impaired renal function or an increase in the QT interval of more than 15%, or 500 milliseconds. The drug should not be given to patients with a creatinine clearance lower than 20 mL/min or a baseline QTc interval longer than 440 milliseconds.

INDICATIONS. Oral dofetilide is indicated for prevention of episodes of supraventricular tachyarrhythmias, particularly atrial flutter and fibrillation. The role of dofetilide in the treatment of ventricular arrhythmias is less clear; it has been shown to decrease the defibrillation threshold in patients with an ICD, as well as decrease the frequency of ICD therapies for ventricular arrhythmias.¹⁸

ADVERSE EFFECTS. The most significant adverse effect of dofetilide is QT interval prolongation–related torsades de pointes, which occurs in 2% to 4% of patients given the drug. Risk is highest in patients with a baseline prolonged QT interval, in those who are hypokalemic, in those taking some other agent that prolongs repolarization, and after conversion from atrial fibrillation to sinus rhythm. Because the risk for torsades de pointes is highest at the time of drug initiation, it should be used continuously and not as intermittent outpatient dosing. The drug is otherwise well tolerated, with few side effects. Its use in pregnancy has not been studied extensively, and it should probably be avoided in this setting if possible.

Class IV Agents

Calcium Channel Antagonists: Verapamil and Diltiazem

Verapamil, a synthetic papaverine derivative, is the prototype of a class of drugs that block the slow calcium channel and reduce I_{CaL} in cardiac muscle (see Chapter 33). Diltiazem has electrophysiologic actions similar to those of verapamil. Nifedipine and other dihydropyridine agents exhibit minimal electrophysiologic effects at clinically used doses; these drugs are not discussed here.

Electrophysiologic Actions. By blocking I_{CaL} in all cardiac fibers, verapamil reduces the plateau height of the action potential, slightly shortens muscle action potential, and slightly prolongs Purkinje fiber action potential (see Tables 35-1, 35-2, 35-3, and 35-5). It does not appreciably affect the action potential amplitude, V_{max} of phase 0, or resting membrane voltage in cells that have fast-response characteristics related to I_{Na} (e.g., atrial and ventricular muscle, the His-Purkinje system). Verapamil suppresses slow responses elicited by various experimental methods, as well as sustained triggered activity and early and late afterdepolarizations. Verapamil and diltiazem suppress electrical activity in the normal sinus and AV nodes. Verapamil depresses the slope of diastolic depolarization in sinus node cells, V_{max} of phase 0, and maximum diastolic potential and prolongs conduction time and refractory periods of the AV node. The AV node–blocking effects of verapamil and diltiazem are more apparent at faster rates of stimulation (use dependence) and in depolarized fibers (voltage dependence). Verapamil slows activation of the slow channel and delays its recovery from inactivation.

Verapamil does exert some local anesthetic activity because the *d*-isomer of the clinically used racemic mixture exerts slight blocking effects on I_{Na} . The *l*-isomer blocks the slow inward current carried by calcium, as well as other ions, traveling through the slow channel. Verapamil does not affect calcium-activated adenosine triphosphatase, nor does it block beta receptors, but it may block alpha receptors and potentiate vagal effects on the AV node. Verapamil may also cause other effects that indirectly alter cardiac electrophysiology, such as decreasing platelet adhesiveness or reducing the extent of myocardial ischemia.

In humans, verapamil prolongs conduction time through the AV node (the A-H interval) and lengthens AV nodal anterograde and

retrograde refractory periods without affecting the P wave or QRS duration or the H-V interval. The spontaneous sinus rate may decrease slightly, an effect only partially reversed by atropine. More commonly, the sinus rate does not change significantly because verapamil causes peripheral vasodilation, transient hypotension, and reflex sympathetic stimulation, which mitigates any direct slowing effect that verapamil exerts on the sinus node. If verapamil is given to a patient who is also receiving a beta blocker, the sinus node discharge rate may slow because reflex sympathetic stimulation is blocked. Verapamil does not exert a significant direct effect on atrial or ventricular refractoriness or on the anterograde or retrograde properties of accessory pathways. However, reflex sympathetic stimulation after intravenous verapamil administration may increase the ventricular response over the accessory pathway during atrial fibrillation in patients with Wolff-Parkinson-White syndrome, sometimes dangerously so.

Hemodynamic Effects. Because verapamil interferes with excitation-contraction coupling, it inhibits vascular smooth muscle contraction and causes marked vasodilation in coronary and other peripheral vascular beds. The reflex sympathetic effects of verapamil may reduce its marked negative inotropic action on isolated cardiac muscle, but the direct myocardial depressant effects of verapamil may predominate when the drug is given in high doses. In patients with well-preserved left ventricular function, combined therapy with propranolol and verapamil appears to be well tolerated, but beta blockade can accentuate the hemodynamic depressant effects produced by oral verapamil. Patients with reduced left ventricular function may not tolerate the combined blockade of beta receptors and calcium channels; thus, in these patients, verapamil and propranolol should be used in combination either cautiously or not at all. Verapamil reduces myocardial oxygen demand while decreasing coronary vascular resistance. Such changes may be indirectly antiarrhythmic.

Peak alterations in hemodynamic variables occur 3 to 5 minutes after completion of a verapamil injection, with the major effects dissipating within 10 minutes. Systemic resistance and mean arterial pressure decrease, as does left ventricular dP/dt_{max} , and left ventricular end-diastolic pressure increases. Heart rate, cardiac index, and mean pulmonary artery pressure do not change significantly in individuals with normal resting left ventricular systolic function. Thus the afterload reduction produced by verapamil significantly counterbalances its negative inotropic action, so the cardiac index may not be reduced. In addition, when verapamil slows the ventricular rate in a patient with tachycardia, hemodynamics may also improve. Nevertheless, caution should be exercised in giving verapamil to patients with severe myocardial depression or those receiving beta blockers or disopyramide because hemodynamic deterioration may progress in some patients.

Pharmacokinetics. After single oral doses of verapamil, measurable prolongation of AV nodal conduction time occurs in 30 minutes and lasts 4 to 6 hours (see Table 35-4). After intravenous administration, AV nodal conduction delay occurs within 1 to 2 minutes and A-H interval prolongation is still detectable after 6 hours. After oral administration, absorption is almost complete, but its overall bioavailability of 20% to 35% suggests substantial first-pass metabolism in the liver, particularly of the *l*-isomer. The drug's elimination half-life is 3 to 7 hours, with up to 70% of the drug being excreted by the kidneys. Norverapamil is a major metabolite that may contribute to the electrophysiologic actions of verapamil. Serum protein binding is approximately 90%. With diltiazem, the percentage of heart rate reduction in atrial fibrillation is related to its plasma concentration.

DOSAGE AND ADMINISTRATION. For acute termination of SVT or rapid achievement of ventricular rate control during atrial fibrillation, the most commonly used intravenous dose of verapamil is 10 mg infused over a 1- to 2-minute period while cardiac rhythm and blood pressure are monitored (see Table 35-4). A second injection of an equal dose may be given 30 minutes later. The initial effect achieved with the first bolus injection, such as slowing of the ventricular response during atrial fibrillation, can be maintained by continuous infusion of the drug at a rate of 0.005 mg/kg/min. The oral dose is 240 to 480 mg/day in divided doses. Diltiazem is given intravenously at a dose of 0.25 mg/kg as a bolus over a 2-minute period, with a second dose in 15 minutes if necessary; because it is generally better tolerated (less hypotension) with long-term administration, such as for control of the ventricular rate during atrial fibrillation, diltiazem is preferred over verapamil in this setting. Significant hypotension resulting from intravenous diltiazem can be countered by volume expansion or the judicious use of a pure

vasoconstrictor agent such as phenylephrine. Orally, doses must be adjusted to the patient's needs, with a 120- to 360-mg range. Various long-acting preparations (once daily) are available for verapamil and diltiazem.

INDICATIONS. After simple vagal maneuvers have been tried and adenosine has been given, intravenous verapamil or diltiazem is the next treatment of choice for termination of sustained AV node reentry or orthodromic AV reciprocating tachycardia associated with an accessory pathway (see Chapter 37). Verapamil is as effective as adenosine for termination of these arrhythmias. Assuming that the patient is stable, verapamil should definitely be tried before termination is attempted by digitalis administration, pacing, electrical direct-current cardioversion, or acute blood pressure elevation with vasopressors. Verapamil and diltiazem terminate 60% to 90% or more episodes of paroxysmal SVT within several minutes. Verapamil may also be of use in some fetal SVTs. Although intravenous verapamil has been given along with intravenous propranolol, this combination should be used only with great caution because of combined adverse hemodynamic effects.

Verapamil and diltiazem decrease the ventricular response over the AV node during atrial fibrillation or atrial flutter, possibly converting a small number of episodes to sinus rhythm, particularly if the atrial flutter or fibrillation is of recent onset. In addition, verapamil may prevent early recurrence of atrial fibrillation after electrical cardioversion. Atrial fibrillation may develop in some patients with atrial flutter after verapamil administration. As noted earlier, in patients with preexcited ventricular complexes during atrial fibrillation associated with Wolff-Parkinson-White syndrome, intravenous verapamil may accelerate the ventricular response; therefore the intravenous route is contraindicated in this situation. Verapamil can terminate some ATs. Even though verapamil can often terminate an idiopathic left septal VT, hemodynamic collapse can occur if intravenous verapamil is given to patients with the more common forms of VT because they generally occur in the setting of decreased left ventricular systolic function. A general rule for avoiding complications, however, is to not administer verapamil intravenously to any patient with wide-QRS tachycardia unless one is absolutely certain of the nature of the tachycardia and its probable response to verapamil.

Orally, verapamil or diltiazem can prevent the recurrence of AV node reentrant and orthodromic AV reciprocating tachycardias associated with an accessory pathway, as well as help maintain a decreased ventricular response during atrial flutter or atrial fibrillation in patients without an accessory pathway. Verapamil has not generally been effective in treating patients who have recurrent ventricular tachyarrhythmias, although it may suppress some forms of VT, such as left septal VT (noted earlier). It may also be useful in about two thirds of patients with idiopathic VT that has a left bundle branch block morphology (right ventricular outflow tract origin), patients with hypertrophic cardiomyopathy who have experienced cardiac arrest, patients with a short-coupled variant of polymorphic VT, and patients with ventricular arrhythmias related to coronary artery spasm. Calcium channel blockers have not been shown to reduce mortality or to prevent sudden cardiac death in patients after acute myocardial infarction, except for diltiazem in those with non-ST-segment elevation infarctions (see Chapter 53).

ADVERSE EFFECTS. Verapamil must be used cautiously in patients with significant hemodynamic impairment or in those receiving beta blockers, as noted earlier. Hypotension, bradycardia, AV block, and asystole are more likely to occur when the drug is given to patients who are already receiving beta-blocking agents. Hemodynamic collapse has been noted in infants, and verapamil should be used cautiously in children younger than 1 year. Verapamil should also be used with caution in patients with sinus node abnormalities because marked depression of sinus node function or asystole can result in some of these patients. Intravenous isoproterenol, calcium, glucagon, dopamine, or atropine, which may be only partially effective, or temporary pacing may be necessary to counteract some of the adverse effects of verapamil. Isoproterenol may be more effective for the treatment of bradyarrhythmias, and calcium may be used for the treatment of hemodynamic dysfunction secondary to verapamil. AV

node depression is common in overdoses. Contraindications to the use of verapamil and diltiazem include the presence of advanced heart failure, second- or third-degree AV block without a pacemaker in place, atrial fibrillation and anterograde conduction over an accessory pathway, significant sinus node dysfunction, most VTs, cardiogenic shock, and other hypotensive states. Although these drugs should probably not be used in patients with overt heart failure, if it is caused by one of the supraventricular tachyarrhythmias noted earlier, verapamil or diltiazem may restore sinus rhythm or significantly decrease the ventricular rate and thereby lead to hemodynamic improvement. Finally, verapamil can decrease the excretion of digoxin by approximately 30%. Hepatotoxicity may occur on occasion. Verapamil crosses the placental barrier; its use in pregnancy has been associated with impaired uterine contraction, fetal bradycardia, and possibly fetal digital defects. It should therefore be used only if no effective alternatives exist.

Other Antiarrhythmic Agents

Adenosine

Adenosine is an endogenous nucleoside present throughout the body and has been approved by the FDA to treat patients with SVTs.

Electrophysiologic Actions. Adenosine interacts with A_1 receptors present on the extracellular surface of cardiac cells and activates K^+ channels ($I_{K, Ach}$, $I_{K, Ado}$) in a fashion similar to that produced by acetylcholine (see [Tables 35-1, 35-2, 35-3, and 35-5](#)). The increase in K^+ conductance shortens the atrial APD, hyperpolarizes the membrane potential, and decreases atrial contractility. Similar changes occur in the sinus and AV nodes. In contrast to these direct effects mediated through the guanine nucleotide regulatory proteins G_i and G_o , adenosine antagonizes catecholamine-stimulated adenylate cyclase to decrease accumulation of cyclic adenosine monophosphate and to decrease $I_{Ca,L}$ and the pacemaker current I_f in sinus node cells along with a decrease in V_{max} . Shifts in the pacemaker site within the sinus node and sinus exit block may occur. Adenosine slows the sinus rate in humans, followed within seconds by a reflex increase in the sinus rate. In the AV node, adenosine produces transient prolongation of the A-H interval, often with transient first-, second-, or third-degree AV node block lasting up to a few seconds. The delay in AV nodal conduction is rate dependent. His-Purkinje conduction is not generally affected directly. Adenosine does not affect conduction in normal accessory pathways. Conduction may be blocked in unusual accessory pathways that have long conduction times or decremental conduction properties. Patients with heart transplants exhibit a supersensitive response to adenosine. Adenosine may mediate the phenomenon of ischemic preconditioning.

Pharmacokinetics. Adenosine is removed from the extracellular space by washout, enzymatically by degradation to inosine, by phosphorylation to adenosine monophosphate, or by reuptake into cells through a nucleoside transport system (see [Table 35-4](#)). The vascular endothelium and erythrocytes contain these elimination systems, which result in very rapid clearance of adenosine from the circulation. Its elimination half-life is 1 to 6 seconds. Most of adenosine's effects are produced during its first passage through the circulation. Important drug interactions occur; methylxanthines are competitive antagonists, and therapeutic concentrations of theophylline totally block the exogenous effects of adenosine. Dipyridamole is a nucleoside transport blocker that blocks reuptake of adenosine, thus delaying its clearance from the circulation or interstitial space and potentiating its effect. Smaller adenosine doses should be used in patients receiving dipyridamole.

DOSAGE AND ADMINISTRATION. To terminate tachycardia, a bolus of adenosine is rapidly injected intravenously at doses of 6 to 12 mg, followed by a flush (see [Table 35-4](#)). Pediatric dosing should be 0.1 to 0.3 mg/kg. When it is injected into a central vein and in patients after heart transplantation or those receiving dipyridamole, the initial dose should be reduced to 3 mg. Transient sinus slowing or AV node block results but lasts less than 5 seconds. Doses higher than 18 mg are unlikely to revert a tachycardia and should not be used.

INDICATIONS. Adenosine has become the drug of first choice to terminate an SVT acutely, such as AV node or AV reentry (see [Chapter 37](#)), and is useful in pediatric patients. Adenosine can produce AV nodal block or terminate ATs and sinus node reentry. It results in only

transient AV block during atrial flutter or fibrillation and is thus useful only for diagnosis, not therapy. Adenosine terminates a group of VTs whose maintenance depends on adrenergic drive, which is most often located in the right ventricular outflow tract but can be found at other sites as well; idiopathic left septal VT rarely responds, however. Adenosine has less potential than verapamil for lowering blood pressure should tachycardia persist after injection.

Doses as low as 2.5 mg terminate some tachycardias; doses of 12 mg or less terminate 92% of SVTs, usually within 30 seconds. Successful termination rates with adenosine are comparable to those achieved with verapamil. Because of its effectiveness and extremely short duration of action, adenosine is preferable to verapamil in most cases, particularly in patients who have previously received intravenous beta adrenoceptor blockers, in those with poorly compensated heart failure or severe hypotension, and in neonates. Verapamil might be chosen first in patients receiving drugs such as theophylline (which is known to interfere with adenosine's actions or metabolism), in patients with active bronchoconstriction, and in those with inadequate venous access.

Adenosine may be useful to help differentiate among causes of wide-QRS tachycardias because it terminates many SVTs with aberrancy or reveals the underlying atrial mechanism and does not block conduction over an accessory pathway or terminate most VTs. However, in rare cases adenosine terminates some VTs, characteristically those of right ventricular outflow tract origin as noted earlier, and therefore tachycardia termination is not completely diagnostic of an SVT. This agent may predispose to the development of atrial fibrillation and might transiently increase the ventricular response in patients with atrial fibrillation conducting over an accessory pathway. Adenosine may also be useful in differentiating conduction over the AV node from that over an accessory pathway during ablative procedures designed to interrupt the accessory pathway. However, this distinction is not absolute because adenosine can block conduction in slowly conducting accessory pathways and does not always produce block in the AV node.

ADVERSE EFFECTS. Transient side effects occur in almost 40% of patients with SVT given adenosine and most commonly consist of flushing, dyspnea, and chest pressure. These symptoms are fleeting, lasting less than 1 minute, and are well tolerated. PVCs, transient sinus bradycardia, sinus arrest, and AV block are common when an SVT is terminated abruptly. Atrial fibrillation is occasionally observed (12% in one study) with adenosine administration, perhaps because of the drug's effect in shortening atrial refractoriness. Induction of atrial fibrillation can be problematic in patients with Wolff-Parkinson-White syndrome and rapid AV conduction over the accessory pathway.

Digoxin

Cardiac actions of digitalis glycosides have been recognized for centuries. Digoxin is used for control of supraventricular arrhythmias, mainly control of the ventricular rate during atrial fibrillation. Use of digoxin has decreased because of the availability of agents with greater potency and a wider therapeutic to toxic drug concentration range.

Electrophysiologic Actions. Digoxin acts mainly through the autonomic nervous system, in particular, by enhancing both central and peripheral vagal tone. These actions are confined largely to slowing of the sinus node discharge rate, shortening of atrial refractoriness, and prolongation of AV nodal refractoriness (see [Tables 35-1, 35-2, 35-3, and 35-5](#)). Electrophysiologic effects on the His-Purkinje system and ventricular muscle are minimal, except with toxic concentrations. In studies of denervated hearts, digoxin has relatively little effect on the AV node and causes a mild increase in atrial refractoriness.

The sinus rate and P wave duration are minimally changed in most patients taking digoxin. The sinus rate may decrease in patients with heart failure whose left ventricular performance is improved by the drug; individuals with significant underlying sinus node disease also have slower sinus rates or even sinus arrest. Similarly, the PR interval is generally unchanged, except in patients with underlying AV node disease. The QRS and QT intervals are unaffected. The characteristic ST and T wave abnormalities seen with use of digoxin do not represent toxicity.

Pharmacokinetics. Intravenously administered digoxin yields some electrophysiologic effect within minutes, with a peak effect occurring after 1.5 to 3 hours (see Table 35-4). After oral dosing, the peak effect occurs in 4 to 6 hours. The extent of digoxin absorption after oral administration varies according to the preparation; tablet forms are 60% to 75% absorbed, whereas encapsulated gel forms are almost completely absorbed. Ingestion of cholestyramine or an antacid preparation at the same time as digoxin ingestion decreases its absorption. The serum half-life of digoxin is 36 to 48 hours, and the drug is excreted unchanged by the kidneys.

DOSAGE AND ADMINISTRATION. In acute loading doses of 0.5 to 1.0 mg, digoxin may be given orally or intravenously (see Table 35-4). Chronic daily oral dosing should be adjusted on the basis of clinical indications and the extent of renal dysfunction. Most patients require 0.125 to 0.25 mg/day as a single dose. However, as little as 0.125 mg every other day is needed in some patients undergoing renal dialysis, whereas young patients may require as much as 0.5 mg/day. Serum digoxin levels may be used to monitor compliance with therapy, as well as to determine whether digitalis toxicity is the cause of new symptoms compatible with the diagnosis. However, routine monitoring of digoxin levels is not warranted in patients whose ventricular rate is controlled during atrial fibrillation and who have no symptoms of toxicity.

INDICATIONS. Digoxin can be used intravenously to slow the ventricular rate during atrial fibrillation and flutter; it was formerly used in an attempt to convert SVTs to sinus rhythm, but its onset of action is much slower and its success rate less than that of adenosine, verapamil, or beta blockers. Thus it is now rarely used in this fashion. Digoxin is more commonly used orally to control the ventricular rate in permanent ("chronic") atrial fibrillation. When a patient with atrial fibrillation is at rest and vagal tone predominates, the ventricular rate can be maintained at between 60 and 100 beats/min in 40% to 60% of cases. However, when the patient begins to exercise, the decrease in vagal tone and increase in adrenergic tone combine to diminish the beneficial effects of digoxin on AV nodal conduction. Patients may experience a marked increase in ventricular rate with even mild exertion. Digoxin is therefore rarely used as a single agent to control the ventricular rate in atrial fibrillation. The drug has little ability to prevent episodes of paroxysmal atrial fibrillation or to control the ventricular rate during episodes and may even provoke episodes in patients with so-called vagal atrial fibrillation. Finally, digoxin is no more effective than placebo in terminating episodes of acute- or recent-onset atrial fibrillation.

ADVERSE EFFECTS. One major reason that use of digoxin has decreased is its potential for serious adverse effects and the narrow window between therapeutic and toxic concentrations. Digitalis toxicity produces various symptoms and signs, including headache, nausea and vomiting, altered color perception, halo vision, and generalized malaise. Less common but more serious than these are digitalis-related arrhythmias, which include bradycardias related to a markedly enhanced vagal effect (e.g., sinus bradycardia or arrest, AV node block) and tachyarrhythmias that may be caused by delayed afterdepolarization-mediated triggered activity (e.g., atrial, junctional, and fascicular or ventricular tachycardia). Worsening renal function, advanced age, hypokalemia, chronic lung disease, hypothyroidism, and amyloidosis increase a patient's sensitivity to digitalis-related arrhythmias. The diagnosis can be confirmed by determination of the serum digoxin level. Therapy for most bradycardias consists of withdrawal of digoxin; atropine or temporary pacing may be needed in symptomatic patients. Phenytoin can be used for control of atrial tachyarrhythmias, whereas lidocaine has been successful in treating infranodal tachycardias. Life-threatening arrhythmias can be treated with digoxin-specific antibody fragments. Electrical direct-current cardioversion should be performed only when absolutely necessary in a digitalis-toxic patient because life-threatening VT or VF can result and be very difficult to control. Some data incriminate digoxin in increasing mortality in patients with atrial fibrillation.

Ranolazine

Ranolazine, approved by the FDA for the treatment of chronic angina, has significant electrophysiologic properties. It has been shown to

decrease the incidence of atrial fibrillation, SVT, and ventricular arrhythmias relative to controls in trials of the drug's antianginal effects.

Electrophysiologic Actions. Ranolazine blocks I_{Kr} , as well as the late Na current; at higher concentrations, the L-type Ca current is mildly affected (see Tables 35-1, 35-2, 35-3, 35-5). The drug prolongs atrial and ventricular refractoriness and induces postrepolarization refractoriness; the P wave, PR interval, and QRS are unaffected, but the QT interval is mildly prolonged. Unlike other I_{Kr} -blocking drugs, ranolazine does not induce early afterdepolarizations.¹⁹ Its effects are more pronounced on atrial than on ventricular myocardium, and the drug shows great promise for the treatment of atrial fibrillation.

Hemodynamic Effects. Ranolazine has no important hemodynamic effects; it does not appear to produce meaningful changes in contractility or vascular resistance.

Pharmacokinetics. Absorption of orally administered ranolazine is mediated in part by the P-glycoprotein system, modulators of which may increase or decrease exposure to the drug. About 75% of a dose is bioavailable, with peak levels being reached in 2 to 5 hours (see Table 35-4). Absorption is not affected by food. Its half-life is approximately 7 hours; hepatic metabolism to minimally or wholly inactive products occurs via the CYP3A and, to a lesser extent, the CYPD4 pathways. Approximately 75% of the drug is excreted in urine, the remainder in feces.

DOSAGE AND ADMINISTRATION. The typical oral dose is 500 mg twice daily, to a maximum of 1000 mg twice daily. The dose should be decreased in the setting of moderate liver disease. It should not be used in conjunction with strong inhibitors of CYP3A, which could increase the drug's serum concentration threefold.

ADVERSE EFFECTS. The most widely known potential adverse effect of the drug is QTc prolongation, which averages 6 to 15 milliseconds (sometimes more in patients with severe liver failure), because of inhibition of I_{Kr} . Despite this effect on the QT interval, torsades de pointes is very rare. This is probably due in part to only modest QT prolongation combined with the drug's inhibition of the late inward Na current, which mitigates the QT effect. As noted above, ranolazine does not cause early afterdepolarizations or increases in transmural dispersion of refractoriness, which are believed to be prerequisites for torsades. Ranolazine produces a mild elevation in measured serum creatinine (0.1 mg/dL) without changing the actual glomerular filtration rate. The drug is pregnancy category C; its concentration in breast milk is unknown.

Antiarrhythmic Effects of Nonantiarrhythmic Drugs

Several medications commonly used for other indications also have some degree of antiarrhythmic effect. In some cases, physicians can use these drugs for their standard indications and achieve additional, although often small, amounts of benefit in treating the patient's rhythm disturbance. Among these drugs are angiotensin-converting enzyme inhibitors and angiotensin receptor–blocking agents, aldosterone antagonists such as eplerenone, statins and omega-3 fatty acids (prevention of sudden death), and these same classes of drugs with the addition of nondihydropyridine calcium channel blockers and ranolazine (less atrial fibrillation and perhaps VF).²⁰ The mechanisms whereby these drugs exert their attenuating effect on arrhythmias is not clear in most cases, and they should not be relied on as the sole form of antiarrhythmic therapy. In patients who have arrhythmias, as well as another disorder that requires drug therapy (hypertension, heart failure), one of these medications may be preferable to agents that treat the primary disorder but do not possess antiarrhythmic effects.

ELECTROTHERAPY FOR CARDIAC ARRHYTHMIAS

Direct-Current Electrical Cardioversion

Cardioversion is a general term used to indicate the termination of an arrhythmia, usually a tachyarrhythmia, by various means, including electrical, pharmacologic, or manual/surgical. Electrical

cardioversion refers to the delivery of an electrical shock to the heart to terminate a tachycardia, flutter, or fibrillation and includes the technique of both synchronous cardioversion (see below) and defibrillation. It offers obvious advantages over drug therapy because under conditions optimal for close supervision and monitoring, a precisely regulated “dose” of electricity can restore sinus rhythm immediately and safely. The distinction between supra-ventricular and ventricular tachyarrhythmias, crucial to the proper medical management of arrhythmias, becomes less significant, and the time-consuming titration of drugs with potential side effects is obviated.

Mechanisms. Electrical cardioversion is most effective in terminating tachycardias related to reentry, such as atrial flutter and many cases of atrial fibrillation, AV node reentry, reciprocating tachycardias associated with Wolff-Parkinson-White syndrome, most forms of VT, ventricular flutter, and VF. The electrical shock, by depolarizing all excitable myocardium and possibly by prolonging refractoriness, interrupts reentrant circuits and establishes electrical homogeneity, which terminates reentry. The mechanism by which a shock successfully terminates VF has not been completely explained. If the precipitating factors are no longer present, interruption of the tachyarrhythmia for only the brief time produced by the shock may prevent its return for long periods, even though the anatomic and electrophysiologic substrates required for the tachycardia are still present.

Tachycardias thought to be caused by disorders of impulse formation (automaticity) include parastole, some forms of AT, ectopic junctional tachycardia (with or without digitalis toxicity), accelerated idioventricular rhythm, and relatively uncommon forms of VT (see Chapters 33 and 37). An attempt to cardiovert these tachycardias electrically is not indicated in most cases because they typically recur within seconds after the shock; release of endogenous catecholamines consequent to the shock may further exacerbate the arrhythmia. It has not been established whether cardioversion can terminate tachycardias caused by enhanced automaticity or triggered activity.

Technique. Synchronous cardioversion refers to a specific technique of delivering an electrical shock, usually of lower energy and timed to the QRS complex (“R wave”), to avoid the vulnerable period of the T wave. Before elective synchronous cardioversion, careful physical examination, including palpation of limb pulses and inspection of the chest wall and airway, should be performed. A 12-lead ECG is obtained before and after cardioversion, as well as a rhythm strip during the electroshock. The patient, who should be informed completely about what to expect, is in a fasting state and metabolically balanced; that is, respiratory function and electrolyte values should be normal, with no evidence of drug toxicity. Withholding of digitalis for several days before elective cardioversion in patients without clinical evidence of digitalis toxicity is not necessary, although patients in whom digitalis toxicity is suspected should not be electrically cardioverted until this situation has been corrected. Administration of maintenance antiarrhythmic drugs 1 to 2 days before planned electrical cardioversion of patients with atrial fibrillation can revert some patients to sinus rhythm, help prevent recurrence of atrial fibrillation once sinus rhythm is restored, and assist in determining the patient’s tolerance of the drug for long-term use.²¹ There is also evidence that statin drugs,²² as well as angiotensin-converting enzyme inhibitors and receptor blockers, may help prevent recurrence of fibrillation, especially in patients with ventricular dysfunction.

Self-adhesive patches applied in the standard apicoanterior or anteroposterior paddle positions have transthoracic impedances similar to those of paddles and are useful in elective synchronous cardioversions or other situations in which time is available for their

FIGURE 35-1 Cardioversions. In **A**, a synchronized shock (note the synchronization mark in the apex of the QRS complex [arrowhead]) during atrial flutter is followed by sinus bradycardia. In **B**, top panel, a shock (#1) is delivered during VT but asynchronously (on the T wave); this results in VF, which is then treated with a second, asynchronous shock (#2) that results in sinus rhythm with tracked ventricular pacing. Resp = respirations.

application. Patches 12 to 13 cm in diameter can be used to deliver maximum current to the heart, but the benefits of these patches versus patches 8 to 9 cm in diameter have not been clearly established. Larger patches may distribute the intracardiac current over a wider area and reduce shock-induced myocardial injury.

A synchronized shock (i.e., one delivered during the QRS complex; Fig. 35-1) is used for all cardioversions except for very rapid ventricular tachyarrhythmias, such as ventricular flutter or VF. For defibrillation of the latter, energies greater than those for synchronous cardioversion are required, and synchronization is not necessary because there is no vulnerable period of the T wave to avoid. Although generally minimal, shock-related myocardial damage increases directly with increases in applied energy, and thus the minimum effective shock should be used. Therefore, shocks are “titrated” when the clinical situation permits. Except for atrial fibrillation, shocks in the range of 25 to 50 J successfully terminate most SVTs and should be tried initially. If the shock is unsuccessful, a second shock of higher energy can be delivered. The starting level to terminate atrial fibrillation with older monophasic machines should be no less than 100 J, but with newer biphasic systems, a shock as low as 25 J may succeed.²³ Delivered energy can be increased in stepwise fashion; up to 360 J can be used safely. It is critical to remember to resynchronize the defibrillator to the QRS complex after an unsuccessful shock before delivery of another shock to avoid initiation of VF (machines typically revert to the asynchronous mode after each shock). Anteroposterior patches may have a higher efficacy rate by placing more of the atrial mass in the shock vector than is the case with apicoanterior patches. If a shock of 360 J fails to convert the rhythm, repeated shocks at the same energy may succeed by decreasing chest wall impedance; reversing patch polarity can occasionally help as well. Administration of ibutilide has been shown to facilitate electrical cardioversion of atrial fibrillation to sinus rhythm. Intracardiac or transesophageal defibrillation can be tried if all attempts at external cardioversion fail. For patients with stable VT, starting levels in the range of 25 to 50 J can be used. If there is some urgency to terminate the tachyarrhythmia, one can begin with higher energies. To terminate VF, 100 to 200 J (biphasic; 200 to 360 J with monophasic machines) is generally used, although much lower energies (<50 J) terminate VF when the shock is delivered soon after onset of the arrhythmia, for example, using adhesive patches in the electrophysiology laboratory.

During elective cardioversion, a short-acting barbiturate such as methohexital, a sedative such as propofol, or an amnesic such as

diazepam or midazolam can be used. A physician skilled in airway management should be in attendance; an intravenous route should be established; and pulse oximetry, the ECG, and blood pressure should be monitored. All equipment necessary for emergency resuscitation should be immediately accessible. Before cardioversion, 100% oxygen may be administered for 5 to 15 minutes by nasal cannula or facemask and is continued throughout the procedure. Manual ventilation of the patient may be necessary to avoid hypoxia during periods of deepest sedation. Adequate sedation of the patient undergoing even urgent cardioversion is essential.

In up to 5% of patients with atrial fibrillation, sinus rhythm cannot be restored by external countershock despite all the preceding measures, including ibutilide pretreatment and biphasic shocks. It is important to distinguish between inability to attain sinus rhythm, indicating inadequate delivery of energy to the atria, and inability to maintain sinus rhythm after transient termination of fibrillation; the latter condition (early reinitiation of atrial fibrillation) does not respond to higher-energy shocks because fibrillation has already been terminated but quickly recurs. Pretreatment with an antiarrhythmic drug may help maintain sinus rhythm after subsequent shocks. Patients in whom atrial fibrillation simply cannot be terminated with an external shock tend to be very obese or have severe obstructive lung disease. In such cases, internal cardioversion can be performed with the use of specially configured catheters that have multiple large electrodes covering several centimeters of the distal portion of the catheter for distributing the shock energy. By standard percutaneous access, these catheters can be situated in the lateral part of the right atrium and coronary sinus to achieve a shock vector across most of the atrial mass. With such configurations, internal shocks of 2 to 15 J can terminate atrial fibrillation in more than 90% of patients whose arrhythmia is refractory to transthoracic shock. Esophageal cardioversion has also been reported. Rarely, simultaneous shocks from two defibrillators have been reported to terminate refractory VF.

Indications

As a rule, any nonsinus tachycardia that produces hypotension, congestive heart failure, mental status changes, or angina and does not respond promptly to medical management should be terminated electrically. Very rapid ventricular rates in patients with atrial fibrillation and Wolff-Parkinson-White syndrome are often best treated by electrical cardioversion. In almost all cases the patient's hemodynamic status improves after cardioversion. Rarely, a patient may experience hypotension, reduced cardiac output, or congestive heart failure after the shock. This problem may be related to complications of the cardioversion, such as embolic events, myocardial depression resulting from the anesthetic agent or the shock itself, hypoxia, lack of restoration of left atrial contraction despite return of electrical atrial systole, or postshock arrhythmias. Direct-current countershock of digitalis-induced tachyarrhythmias is contraindicated.

Favorable candidates for electrical cardioversion of atrial fibrillation include patients who (1) have symptomatic atrial fibrillation of less than 12 months' duration, (2) continue to have atrial fibrillation after the precipitating cause has been removed (e.g., after treatment of thyrotoxicosis), (3) have a rapid ventricular rate that is difficult to slow, or (4) have symptoms of decreased cardiac output (e.g., fatigue, lightheadedness, dyspnea) attributable to lack of atrial contraction's contribution to ventricular filling. In patients who have indications for chronic warfarin therapy to prevent stroke, the hope of avoiding anticoagulation by restoring sinus rhythm is not a reason to attempt cardioversion because these patients are still at increased risk for thromboembolic events. Several large trials have shown that maintenance of sinus rhythm confers no survival advantage over rate control and anticoagulation; thus, not all patients with newly discovered atrial fibrillation warrant an attempt at restoration of sinus rhythm. Treatment must be determined individually.

Unfavorable candidates include patients with (1) digitalis toxicity; (2) no symptoms and a well-controlled ventricular rate without therapy; (3) sinus node dysfunction and various unstable supraventricular tachyarrhythmias or bradyarrhythmias—often bradycardia-tachycardia syndrome—in whom atrial fibrillation finally develops and is maintained, which in essence represents a cure for sick sinus syndrome; (4) little or no symptomatic improvement with normal sinus rhythm who promptly revert to atrial fibrillation after

cardioversion despite drug therapy; (5) a large left atrium and long-standing atrial fibrillation; (6) episodes of atrial fibrillation that revert spontaneously to sinus rhythm; (7) no mechanical atrial systole after the return of electrical atrial systole; (8) atrial fibrillation and advanced heart block; (9) cardiac surgery planned in the near future; and (10) antiarrhythmic drug intolerance. Atrial fibrillation is more likely to recur after cardioversion in patients who have significant chronic obstructive lung disease, congestive heart failure, mitral valve disease (particularly mitral regurgitation), atrial fibrillation present longer than 1 year, and an enlarged left atrium (echocardiographic diameter larger than 4.5 cm).

In patients with atrial flutter, slowing the ventricular rate by administration of beta or calcium channel blockers or terminating the flutter with an antiarrhythmic agent may be difficult, and electrical cardioversion is often the initial treatment of choice. For patients with other types of SVT, electrical cardioversion may be used when (1) vagal maneuvers or simple medical management (e.g., intravenous adenosine and verapamil) has failed to terminate the tachycardia and (2) the clinical setting indicates that fairly prompt restoration of sinus rhythm is desirable because of hemodynamic decompensation or electrophysiologic consequences of the tachycardia. Similarly, in patients with VT, the hemodynamic and electrophysiologic consequences of the arrhythmias determine the need for and urgency of direct-current cardioversion. Electrical countershock is the initial treatment of choice for ventricular flutter or VF. Speed is essential (see Chapter 39).

If after the first shock, reversion of the arrhythmia to sinus rhythm does not occur, a higher energy level should be tried. When transient ventricular arrhythmias result after an unsuccessful shock, a bolus of lidocaine can be given before delivery of a shock at the next energy level. If sinus rhythm returns only transiently and is promptly supplanted by the tachycardia, a repeated shock can be tried, depending on the tachyarrhythmia being treated and its consequences. Administration of an antiarrhythmic agent intravenously may be useful before delivery of the next cardioversion shock (such as ibutilide for resistant atrial fibrillation). After cardioversion, the patient should be monitored, at least until full consciousness has been restored and preferably for an hour or more thereafter, depending on the duration of recovery from the particular form of sedation or anesthesia used. If ibutilide has been given, the ECG should be monitored for up to 8 hours because torsades de pointes can develop in the first few hours after administration.

Results

Electrical cardioversion restores sinus rhythm in up to 95% of patients, depending on the type of tachyarrhythmia. However, sinus rhythm remains after 12 months in less than a third to a half of patients with longstanding persistent atrial fibrillation. Thus, maintenance of sinus rhythm, once established, is the difficult problem, not immediate termination of the tachyarrhythmia. The likelihood of maintaining sinus rhythm depends on the particular arrhythmia, the presence of underlying heart disease, and the response to antiarrhythmic drug therapy. Atrial size often decreases after termination of atrial fibrillation and restoration of sinus rhythm, and functional capacity improves.

Complications

Arrhythmias induced by electrical cardioversion are generally caused by inadequate synchronization, with the shock occurring during the ST segment or T wave (see Fig. 35-1). On occasion, a properly synchronized shock can produce VF. Postshock arrhythmias are usually transient and do not require therapy. Asystole is rare and typically lasts no more than a few seconds before a sinus or junctional rhythm ensues; most defibrillators are also capable of transcutaneous pacing if needed. Embolic episodes are reported to occur in 1% to 3% of patients converted from atrial fibrillation to sinus rhythm. Prior therapeutic anticoagulation with warfarin (international normalized ratio [INR], 2.0 to 3.0) or newer agents such as dabigatran, rivaroxaban, or apixaban should be used consistently for at least 3 weeks by patients who have no contraindication to such therapy and

have had atrial fibrillation present for longer than 2 to 3 days or of indeterminate duration. It is important to note that 3 weeks of therapeutic anticoagulation is not the same as simply administering warfarin for 3 weeks because the warfarin dose may not achieve a therapeutic INR. The newer agents confer almost immediate anticoagulation (such that 3 weeks of treatment equals 3 weeks of anticoagulation). Anticoagulation for at least 4 weeks afterward is recommended because restoration of atrial mechanical function lags behind that of electrical systolic function, and thrombi can still form in largely akinetic atria, although they are electrocardiographically in sinus rhythm. Exclusion of left atrial thrombi by transesophageal echocardiography immediately before cardioversion may not always preclude embolism days or weeks after cardioversion of atrial fibrillation. Atrial thrombi can be present in patients with non-fibrillation-related atrial tachyarrhythmias, such as atrial flutter and AT in patients with congenital heart disease. The same precardioversion and postcardioversion anticoagulation recommendations apply to these patients, as well as to those with atrial fibrillation. Although direct-current shock has been demonstrated in animals to cause myocardial injury, studies in humans have indicated that elevations in myocardial enzymes after cardioversion are not common. ST-segment elevation, sometimes dramatic, can occur immediately after elective direct-current cardioversion and last for 1 to 2 minutes, although cardiac enzymes and myocardial scintigraphy may be unremarkable. ST elevation lasting longer than 2 minutes usually indicates myocardial injury unrelated to the shock. A decrease in serum K^+ and Mg^{2+} levels can occur after cardioversion of VT.

Cardioversion of VT can also be achieved by a chest thump. Its mechanism of termination is probably related to a mechanically induced PVC that interrupts a tachycardia circuit and may be related to commotio cordis (see Chapter 79). The thump cannot be timed very well and is probably effective only when delivered during a nonrefractory part of the cardiac cycle. The thump can alter a VT and possibly induce ventricular flutter or VF if it occurs during the vulnerable period of the T wave. Because there may be a slightly greater likelihood of converting a stable VT to VF than of terminating VT to sinus rhythm, chest thump cardioversion should not be attempted unless a defibrillator is simply unavailable.

Implantable Electrical Devices for Treatment of Cardiac Arrhythmias

Implantable devices that monitor the cardiac rhythm and can deliver competing pacing stimuli and low- and high-energy shocks have been used effectively in selected patients (see Chapter 36).

Ablation Therapy for Cardiac Arrhythmias

The purpose of catheter ablation is to destroy myocardial tissue by delivery of energy, generally electrical energy or cryoenergy, through electrodes on a catheter placed next to an area of the myocardium integrally related to onset or maintenance of the arrhythmia. For tachycardias with an apparent focal origin (e.g., automatic, triggered activity, microentry), the focus itself (<5 mm in diameter) is targeted. In macroreentrant AT and VT, inexcitable scar tissue typically separates strands of surviving myocardium, and wave fronts propagate around these scars. The target for ablation is a narrow portion of myocardium between inexcitable areas (e.g., scar, valve annulus; Fig. 35-2). The first catheter ablation procedures were performed with direct-current shocks, but this energy source has been supplanted by radiofrequency (RF) energy, which is delivered from an external generator and destroys tissue by controlled heat production. Lasers and microwave energy sources have been used, but not commonly; cryothermal catheter ablation has been approved for use in

FIGURE 35-2 Strategies for catheter ablation. **A**, Focal tachycardia. At the left, SVT is caused by an atrial focus, with activation emanating in all directions. Ablation of the focus (**right**) eliminates the arrhythmia with minimal disruption of normal activation. **B**, Macroreentrant SVT in setting of previous atrial damage resulting in scar formation. During SVT (**left**), a wave front circulates around a scarred area and through a narrow isthmus between this and another area of scar. Ablation at this critical site (**right**) prevents further reentry.

humans. When a target tissue has been identified by EPS, the tip of the ablation catheter is maneuvered into apposition with this tissue. After stable catheter position and recordings have been ensured, RF energy is delivered between the catheter tip and an indifferent electrode, usually an electrocautery-type grounding pad on the skin of the patient's thigh. Because energies in the RF portion of the electromagnetic spectrum are poorly conducted by cardiac tissue, RF energy instead causes resistive heating in the cells close to the tip of the catheter (i.e., these cells transduce the electrical energy into thermal energy). When tissue temperature exceeds 50°C, irreversible cellular damage and tissue death occur. An expanding front of conducted heat emanates from the region of resistive heating while RF delivery continues over the next 30 seconds and results in the production of a homogeneous, roughly hemispheric lesion of coagulative necrosis 3 to 5 mm in diameter (Fig. 35-3). RF-induced heating of tissue that has inherent automaticity (e.g., His bundle, foci of automatic tachycardias) results in initial acceleration of a rhythm, whereas RF delivery during a reentrant arrhythmia typically causes slowing and termination of the arrhythmia. In most cases, RF delivery is painless, although ablation of atrial or right ventricular tissue can be uncomfortable for some patients.

Cooled-Tip Radiofrequency Ablation. In some situations the catheter can be delivered to the correct location, but conventional RF energy delivery cannot eliminate the tachycardia. In some of these cases the amount of damage—depth or breadth—caused by standard RF energy is inadequate. With the use of standard RF energy, power delivery is usually regulated to maintain a preset catheter tip

FIGURE 35-3 Radiofrequency lesion in human ventricular myocardium (explanted heart at the time of transplantation). A 30-second application of energy was made at the location denoted by arrows, with the tip of the catheter shown. The lesion is 5 mm in diameter and has a well-demarcated border. A central depression in the lesion results from partial desiccation of tissue.

temperature (typically, 55°C to 70°C). Tip temperatures higher than 90°C are associated with coagulation of blood elements on the electrode, which precludes further energy delivery and could also cause these elements to become detached and embolize. Cooling of the catheter tip by internal circulation of liquid or continuous fluid infusion through small holes in the tip electrode can prevent excessive heating of the tip and allow greater delivery of power, thus producing a larger lesion and potentially enhancing efficacy.²⁴ Cooled-tip ablation has been used to good advantage in cases in which standard (4-mm tip) catheter ablation has failed, as well as for primary therapy for atrial flutter and fibrillation and VT associated with structural heart disease, in which additional damage to already diseased areas is not harmful and may be required to achieve the desired result.

Catheter-delivered cryoablation causes tissue damage by freezing cellular structures. Nitrous oxide is delivered to the tip of the catheter, where it is allowed to boil and cool the tip electrode, after which the gas is circulated back to the delivery console. Catheter tip temperature can be regulated, with cooling to as low as –80°C. Cooling to 0°C causes reversible loss of function and can be used as a diagnostic test (i.e., termination of a tachycardia when the catheter is in contact with a group of cells critical to its perpetuation or determining its effect on normal conduction when close to the AV node). The catheter tip can then be cooled more deeply to produce permanent damage and thus cure of the arrhythmia. Cryoablation has been used for pulmonary vein isolation to treat paroxysmal atrial fibrillation by situating a collapsed balloon at the end of a catheter near a pulmonary vein ostium and inflating the balloon with nitrous oxide at –80°C. During cryoballoon occlusion of the vein for 3 to 4 minutes at a time, pulmonary vein isolation can usually be effected with one or two applications.²⁵ Real-time recordings can be done simultaneously to monitor conduction. Cryoablation appears to cause less endocardial damage than RF energy does and may thus engender less risk for thromboemboli after ablation, as well as less chance of esophageal injury with ablation of atrial fibrillation (although not eliminated); however, balloon cryotherapy to isolate right pulmonary veins for the treatment of atrial fibrillation has resulted in phrenic nerve injury, and care must be taken to establish the location of the phrenic nerve. Residual arrhythmias can result (Videos 35-1 and 35-2).

Radiofrequency Catheter Ablation of Accessory Pathways. **Location of Pathways.** The safety, efficacy, and cost-effectiveness of RF catheter ablation of an accessory AV pathway have made ablation the treatment of choice in most adult and many pediatric patients who have AV reentrant tachycardia (AVRT) or atrial flutter or fibrillation associated with a rapid ventricular response over the accessory pathway (see Chapter 37). When RF energy is delivered to an immature heart, the lesion size can increase as the heart grows; however, this has not been shown to cause problems later in life.

An EPS is performed initially to determine that the accessory pathway is part of the tachycardia circuit or capable of rapid AV conduction during atrial fibrillation and to localize the accessory pathway, the optimal site for ablation. Pathways can exist in the right or left free wall or the septum of the heart (Fig. 35-4). Septal accessory pathways are further classified as superoparaseptal, midseptal, and posteroseptal. Pathways classified as posteroseptal are posterior to

FIGURE 35-4 Locations of accessory pathways by anatomic region. The tricuspid and mitral valve annuli are depicted in a left anterior oblique view. Locations of the coronary sinus, AV node, and bundle of His are shown. Accessory pathways may connect the atrial to the ventricular myocardium in any of the regions shown.

the central fibrous body within the so-called pyramidal space, which is bounded by the posterior superior process of the left ventricle and the inferomedial aspects of both atria. Superoparaseptal pathways are found near the His bundle, and accessory pathway activation potential as well as His bundle potential can be recorded simultaneously from a catheter placed at the His bundle region. Midseptal pathways are close to the AV node and can usually be ablated from a right-sided approach; rarely, a left atrial approach is needed. Right posteroseptal pathways insert along the tricuspid ring in the vicinity of the coronary sinus ostium, whereas left posteroseptal pathways are further into the coronary sinus and may be located at a subepicardial site around the proximal coronary sinus, within a middle cardiac vein or coronary sinus diverticulum, or subendocardially along the ventricular aspect of the mitral annulus.

Pathways at all locations and in all age groups can be ablated successfully. Multiple pathways are present in about 5% of patients. Occasional pathways with epicardial locations may be more easily approached from within the coronary sinus. Rarely, pathways can connect an atrial appendage with adjacent ventricular epicardium, 2 cm or more from the AV groove.

Ablation Site. The optimal ablation site can be found by direct recordings of the accessory pathway (Fig. 35-5), although deflections that mimic accessory pathway potentials can be recorded at other sites. The ventricular insertion site can be determined by finding the site of the earliest onset of the ventricular electrogram in relation to the onset of the delta wave. Other helpful guidelines include unfiltered unipolar recordings that register a QS wave and an accessory pathway signal during preexcitation. A major ventricular potential synchronous with onset of the delta wave can be a target site in left-sided preexcitation, whereas earlier ventricular excitation in relation to the delta wave can be found for right-sided preexcitation. The atrial insertion site of manifest or concealed pathways (i.e., delta wave present or absent, respectively) can be found by locating the site showing the earliest atrial activation during retrograde conduction over the pathway. Reproducible mechanical inhibition of accessory pathway conduction during catheter manipulation and subthreshold stimulation has also been used to determine the optimal site. Accidental catheter trauma should be avoided, however, because it can hide the target for prolonged periods. Right free wall and superoparaseptal pathways are particularly susceptible to catheter trauma.

Left-sided accessory pathways typically cross the mitral annulus obliquely. Consequently, the earliest site of retrograde atrial activation and the earliest site of anterograde ventricular activation are not directly across the AV groove from each other (i.e., ventricular insertion closer to coronary sinus ostium). Identification of the earliest site of atrial activation is usually performed during orthodromic AVRT or relatively rapid ventricular pacing so that retrograde conduction using the AV node does not confuse assessment of the location of the earliest atrial activation.

Successful ablation sites should exhibit stable fluoroscopic and electrical characteristics. During sinus rhythm, local ventricular activation at the successful ablation site precedes onset of the delta wave on the ECG by 10 to 35 milliseconds; during orthodromic AVRT, the interval between onset of ventricular activation in any lead and local atrial activation is usually 70 to 90 milliseconds (see Fig. 35-5). When temperature-measuring ablation catheters are used, a stable rise in catheter tip temperature is a helpful indicator of catheter stability and adequate contact between the electrode and tissue. In such a case,

**VIDEO 35-1**

Macroreentrant left atrial tachycardia after pulmonary vein isolation (still image). The left atrium is viewed from the posterior perspective showing 4 pulmonary veins (PVs)—left (L), right (R), inferior (I), and superior (S). The color scheme indicates the sequence of activation (*red, orange, yellow, green, blue, and purple* before returning to red) during reentry around the right PV following isolation a few months earlier. *Gray regions* represent dense scarring.

VIDEO 35-2

Macroreentrant left atrial tachycardia after pulmonary vein isolation in the same patient as in Video 35-1. A moving *red band* indicates the advancing wavefront of activation throughout one cycle of reentry. This can be seen traveling toward the bottom of the left atrium, then spreading to left and right, sweeping upward, and finally back to a relatively narrow region representing the diastolic corridor, before starting another cycle.

FIGURE 35-5 Wolff-Parkinson-White syndrome. Surface ECG leads 1, 3, V_1 , and V_6 are shown, with intracardiac recordings from high right atrium (HRA), distal His (His_{dist}) bundle region, proximal (CS_{prox}) and distal (CS_{dist}) coronary sinus, right ventricular apex (RVA), and unipolar (Abl_{uni}) and bipolar (Abl_{bi}) tip electrodes of the ablation catheter. RF power in watts (RF_{watts}) is also shown. **A**, Two beats of atrial pacing are conducted over the accessory pathway (blue arrowheads in the Abl_{bi} recording from the site of the accessory pathway) and resulted in a delta wave on the ECG; a premature atrial stimulus (center) encounters accessory pathway refractoriness (red arrowhead) and instead is conducted over the AV node and bundle of His and resulted in a narrow QRS complex and started an episode of AVRT. After each narrow QRS complex is an atrial deflection, the earliest portion of which is recorded at the ablation site (green arrowheads). **B**, Ablation of this pathway by delivery of RF energy from the ablation catheter tip. The blue arrowhead denotes the onset of delivery of RF energy; two QRS complexes later, the delta wave is abruptly lost (green arrowhead in lead 3) because of elimination of conduction over the accessory pathway.

tip temperature generally exceeds 50°C. The retrograde transaortic and transseptal approaches have been used with equal success to ablate accessory pathways located along the mitral annulus. Routine performance of an EPS weeks after the ablation procedure is not generally indicated but may be considered in patients who have a recurrent delta wave or symptoms of tachycardia. Catheter-delivered cryoablation can be useful in patients with septal accessory pathways (located near the AV node or His bundle). With use of this system, the catheter tip and adjacent tissue can be reversibly cooled to test a potential site. If accessory pathway conduction fails while normal AV conduction is preserved, deeper cooling can be performed at the site to complete the ablation. If, however, normal AV conduction is worsened, permanent damage is almost always averted by quickly allowing the catheter to rewarm.

Atriofascicular accessory pathways have connections consisting of a proximal, AV node–like portion, which is responsible for conduction

delay and decremental conduction properties, and a long distal segment located along the endocardial surface of the right ventricular free wall, which has electrophysiologic properties similar to those of the right bundle branch. The distal end of the right atriofascicular accessory pathway can insert into the apical region of the right ventricular free wall, close to the distal right bundle branch, or can actually fuse with the latter. Right atriofascicular accessory pathways might represent a duplication of the AV conduction system and can be localized for ablation by recording potentials from the rapidly conducting distal component, which crosses the tricuspid annulus (analogous to the His bundle) and extends to the apical region of the right ventricular free wall. Ablation at such a site on the annulus is usually successful; these pathways are very sensitive to catheter trauma, and the operator must use great care to avoid such trauma.

Indications

Ablation of accessory pathways is indicated in patients who have symptomatic AVRT that is drug resistant or who are drug intolerant or do not desire long-term drug therapy. It is also indicated in patients who have atrial fibrillation or other atrial tachyarrhythmias and a rapid ventricular response by means of an accessory pathway when the tachycardia is drug resistant or in those who are drug intolerant or do not desire long-term drug therapy. Other potential candidates with an accessory pathway include the following: (1) patients with AVRT or atrial fibrillation with rapid ventricular rates identified during an EPS for another arrhythmia; (2) asymptomatic patients with ventricular preexcitation whose livelihood, profession, important activities, insurability, or mental well-being and the public's safety would be affected by spontaneous tachyarrhythmias or by the presence of the electrocardiographic abnormality; (3) patients with atrial fibrillation and a controlled ventricular response by means of the accessory pathway; and (4) patients with a family history of sudden cardiac death. Controversy remains whether all patients with accessory pathways need treatment; however, ablation has such a high success rate and low complication rate that in most centers, patients who need any form of therapy are referred for catheter ablation.

Results

Currently, in the hands of an experienced operator, the success rate for accessory pathway ablation is greater than 95% (slightly less for right free wall pathways, in which stable catheter-tissue contact is more problematic), with a 2% recurrence rate after an apparently successful procedure. There is a 1% to 2% complication rate, including bleeding, vascular damage, myocardial perforation with cardiac tamponade, valve damage, stroke, and myocardial infarction. Heart block occurs in less than 3% of septal pathways. Procedure-related death is very rare.

Radiofrequency Catheter Modification of the Atrioventricular Node for Atrioventricular Nodal Reentrant Tachycardias

AV node reentry is a common cause of SVT episodes (see Chapters 33 and 37). Although controversy still exists about the exact nature of the tachycardia circuit, abundant evidence has indicated that two pathways in the region of the AV node participate, one with relatively fast conduction but long refractoriness and the other with shorter refractoriness but slower conduction. Premature atrial contractions can encounter refractoriness in the fast pathway, conduct down the slow pathway, and reenter the fast pathway retrogradely, thereby initiating AV nodal reentrant SVT (Fig. 35-6). Although this is the most common manifestation of AV node reentry, some patients have what appears to be propagation in the opposite direction in this circuit (anterograde fast, retrograde slow), as well as a “slow-slow” variant. Other, far less common types have been described. Two or more of these variants can exist in the same patient (Fig. 35-7).

Fast Pathway Ablation. Ablation can be performed to eliminate conduction in the fast pathway or the slow pathway. Currently, fast pathway ablation is rarely performed because it is associated with a prolonged PR interval, a higher recurrence rate (10% to 15%), and a slightly higher risk for complete AV block (2% to 5%) than with slow pathway ablation. One uncommon situation in which fast pathway

FIGURE 35-6 AV node reentry. **A**, Two atrial paced complexes from the coronary sinus (CS) are followed by an atrial premature stimulus at a coupling interval of 260 milliseconds and resulted in an A-H interval of 145 milliseconds. **B**, The same atrial drive train is followed by an atrial extrastimulus 10 milliseconds earlier than before (250 milliseconds). This resulted in a marked increase in the A-H interval to 210 milliseconds, after which AVNRT ensues because the extrastimulus encounters block in a “fast” AV node pathway, conducts down a “slow” pathway, and then conducts back up the fast pathway in a repeating fashion. Red arrowheads denote atrial electrograms coincident with QRS complexes, characteristic of the most common type of AV node reentry. Recording was done as in previous figures.

FIGURE 35-7 Three variants of AV node reentrant SVT in the same patient. **Left**, Most common type of AV node SVT (antegrade slow pathway, retrograde fast). Atrial activation is coincident with ventricular activation. **Center**, “Atypical” AV node reentry with antegrade fast pathway conduction and retrograde conduction over a slow pathway. **Right**, A rare variety is shown that consists of antegrade conduction over a slow pathway and retrograde conduction over a second slow pathway. Note the similar atrial activation sequences in the last two (coronary sinus before the right atrium), as distinct from that of slow-fast AV node reentry (coronary sinus and right atrial activation almost simultaneous). Note also the different P-QRS relationships, from simultaneous activation (left, short RP interval) to P in front of the QRS (middle, long RP interval) and P midway in the cardiac cycle (right). Recording was done as in previous figures. CL = cycle length.

ablation may be preferred is for patients who have a markedly prolonged PR interval at rest and no evidence of anterograde fast pathway conduction. In such cases, ablation of the anterograde slow pathway may produce complete AV block, whereas retrograde fast pathway ablation can eliminate SVT without altering AV conduction.

Slow Pathway Ablation. The slow pathway can be located by mapping along the posteromedial tricuspid annulus close to the coronary sinus os. Electrographic recordings are obtained with an atrial-to-ventricular electrogram ratio of less than 0.5 and either a multicomponent atrial electrogram or a recording of possible slow pathway potential. In the anatomic approach, target sites are selected fluoroscopically. A single RF application eliminates slow pathway conduction in many cases, but in others, serial RF lesions may be needed, starting at the most posterior site (near the coronary sinus os) and progressing to the more anterior locus (closer to the His bundle recording site). An accelerated junctional rhythm (Fig. 35-8) usually occurs when RF energy is applied at a site that will result in successful elimination of SVT. The success rate is equivalent with the anatomic and electrographic mapping approaches, and most often, combinations of both are used and yield success rates approaching 100%, with less than a 1% chance of complete heart block. Catheter-delivered cryoablation has been used for the treatment of AVNRT with excellent results and is considered by some to be safer than RF (less chance of permanent AV block) but in most series has a higher rate of SVT recurrence after apparent successful ablation.

Slow pathway ablation results in an increase in the anterograde AV block cycle length and AV node ERP without a change in the A-H interval or retrograde conduction properties of the AV node. Patients in whom slow pathway conduction is completely eliminated almost never have recurrent SVT episodes; approximately 40% of patients can have evidence of residual slow pathway function after successful elimination of sustained AVNRT, usually manifested as persistent dual-AV node physiology and single-AV node echoes during atrial extra-stimulation. The surest endpoint for slow pathway ablation is elimination of sustained AVNRT, with and without an infusion of isoproterenol.

AVNRT recurs in approximately 5% of patients after slow pathway ablation; repeated ablation is almost always successful. In some patients, the ERP of the fast pathway decreases after slow pathway ablation, possibly because of electrotonic interaction between the two pathways. Atypical forms of reentry can result after ablation, as

can apparent parasympathetic denervation, and result in inappropriate sinus tachycardia.

At present, the slow pathway approach is the preferred method for ablation of typical AVNRT. Ablation of the slow pathway is also a safe and effective means for the treatment of atypical forms of AVNRT. In patients with AVNRT undergoing slow pathway ablation, junctional ectopy during application of the RF energy is a sensitive but nonspecific marker of successful ablation; it occurs in longer bursts at effective target sites than at ineffective sites. Ventriculoatrial conduction should be expected during the junctional ectopy, and poor ventriculoatrial conduction or actual block may herald subsequent anterograde AV block. Junctional ectopic rhythm is caused by heating of the AV node and does not occur with cryoablation.

Indications

RF catheter ablation for AVNRT can be considered in patients with recurrent, symptomatic, sustained AVNRT that is drug resistant or who are drug intolerant or do not desire long-term drug treatment. The procedure can also be considered for patients with sustained AVNRT identified during EPS or catheter ablation of another arrhythmia or when there is a finding of dual-AV node pathway physiology and atrial echoes but without AVNRT during EPS in patients suspected of having AVNRT clinically.

Results

Most centers currently use slow pathway ablation, which results in a procedural success rate of 98%, a recurrence rate of less than 2%, and an incidence of heart block requiring permanent pacing of 1% or less.

Ectopic Junctional Tachycardia

Ectopic junctional tachycardia is a rare form of SVT in which the ECG resembles that in AVNRT but is distinct in that (1) the mechanism is automatic, not reentrant and (2) the atrium is clearly not involved in the tachycardia. This disorder is most commonly observed in young healthy individuals, in women more often than in men, and is usually catecholamine dependent. Ablation must be carried out close to the His bundle, and the risk for heart block requiring pacemaker insertion exceeds 5%.

Radiofrequency Catheter Ablation of Arrhythmias Related to the Sinus Node

Reentry in or around the sinus node is an extremely uncommon arrhythmia characterized by episodes of tachycardia with a P wave identical to the sinus P wave, usually with a PR interval longer than in sinus; in physiologic sinus tachycardia, the PR interval remains normal or shortens because of similar catecholamine effects on the sinus and AV nodes. RF energy is applied around the region of the sinus node at sites of early activation, before onset of the P wave, until the tachycardia terminates.

Inappropriate sinus tachycardia is a syndrome characterized by high sinus rates with exercise and at rest. Patients complain of palpitations at all times of day that correlate with inappropriately high sinus rates. They may not respond well to beta blocker therapy because of lack of desired effect or occurrence of side effects. When the sinus node area is to be ablated, it can be identified anatomically and electrophysiologically, and ablative lesions are usually placed between the superior vena cava and crista terminalis at sites of early atrial activation. Intracardiac echocardiography can help in

FIGURE 35-8 AV node slow pathway modification for cure of AV node reentrant SVT. The ablation recording (arrowhead in Abl₁₋₂) shows a slurred deflection between the atrial and ventricular electrogram components; this may represent the AV node slow pathway deflection (but it is not the bundle of His deflection, which is instead recorded from a separate catheter 15 mm away). Shortly after the onset of RF delivery (arrowhead in RF_{Watts}), an accelerated junctional rhythm begins and gradually speeds up further. Retrograde conduction is present during the junctional rhythm. Abl₃₋₄ = proximal electrode recording from ablation catheter. Recording was done as in previous figures.

defining the anatomy and in positioning the ablation catheter. Isoproterenol may be helpful in “forcing” the site of impulse formation to cells with the most rapid discharge rate. Care must be taken to apply RF energy at the most cephalad sites first; initial ablation performed farther down the crista terminalis does not alter the atrial rate at the time but can damage any subsidiary pacemaker regions that may be needed after the sinus node has eventually been ablated.

Indications

Catheter ablation for *paroxysmal* sinus node reentrant tachycardia can be performed in patients who have recurrent symptomatic episodes of sustained SVT that is drug resistant or who are drug intolerant or do not desire long-term drug treatment. Patients with *persistent* inappropriate sinus tachycardia should be considered for ablation only after clear failure of medical therapy because the results of ablation are often less than completely satisfactory. Whenever ablation is performed in the region of the sinus node, the patient should be apprised of the chance of needing a pacemaker after the procedure. Phrenic nerve damage and superior vena caval stenosis are also possibilities.

Results

Sinus node reentrant tachycardia can be ablated successfully in more than 90% of patients. The results are not as good for inappropriate sinus tachycardia; although a good technical result may be obtained at the time of the procedure, symptoms often persist because of recurrence of rapid sinus rates (at or near preablation rates) or for nonarrhythmic reasons. In some, after the atrial rate decreases, an inappropriately rapid junctional rhythm (80 to 90/min) is present; this may point to an overall increased sensitivity of cells with pacemaker capacity to catecholamines in these patients. Multiple ablation sessions are needed in some patients, and approximately 20% eventually undergo pacemaker implantation; however, not all these patients have relief of palpitations despite a normal heart rate.

Radiofrequency Catheter Ablation of Atrial Tachycardia

ATs are a heterogeneous group of disorders; causative factors include rapid discharge of a focus (focal tachycardia) and reentry. The former can occur in anyone, irrespective of the presence of structural abnormalities of the atria, whereas reentrant ATs almost always occur in the setting of structurally damaged atria. Symptoms vary from none, with relatively infrequent or slow ATs in patients without heart disease, to syncope (rapid AT with compromised cardiac function) or heart failure (incessant AT during a period of weeks or months). All forms of AT are amenable to catheter ablation (see Chapter 37).

FIGURE 35-10 Locations of origins of focal ATs. The atria are viewed from the front with the right atrial free wall retracted to show the interior. Structures are labeled as shown; right atrial foci appear in shades of blue, left atrial foci in shades of red.

Focal Atrial Tachycardia. In focal ATs (automatic or triggered foci or microreentry), activation mapping is used to determine the site of the AT by recording the earliest onset of local activation. These tachycardias can behave capriciously and be practically noninducible during EPS despite the patient complaining of multiple daily episodes before the EPS. Approximately 10% of patients can have multiple atrial foci. Sites tend to cluster near the pulmonary veins in the left atrium and the mouths of the atrial appendages and along the crista terminalis on the right (Figs. 35-9A and 35-10; also see Fig. 34-14). Activation times at these sites typically occur only 15 to 40 milliseconds before onset of the P wave on the ECG. Care must be taken to avoid inadvertent damage to the phrenic nerve; its location can be determined by pacing at high current at a candidate site of ablation while observing for diaphragmatic contraction. Ablation should not be performed at a site at which this is seen, if at all possible.

Reentrant Atrial Tachycardia. As noted, these ATs occur more commonly in the setting of structural heart disease, especially after previous surgery involving an atrial incision (repair of congenital heart disease such as an atrial septal defect, Mustard or Senning repair of transposed great vessels, or one of a variety of Fontan repairs for tricuspid atresia and other disorders) or previous atrial ablation (e.g., for atrial fibrillation). The region of slow conduction is typically related to an end of an atriotomy or previous ablation scar, the location of which varies from patient to patient.

Therefore, preprocedural review of operative and ablation procedure reports and careful electrophysiologic mapping are essential. Because reentry within a complete circuit is occurring, activation can be recorded throughout the entire cardiac cycle. The ablation strategy is to identify regions with mid-diastolic atrial activation during tachycardia (Fig. 35-11; also see Fig. 35-9B) that can be proved by pacing techniques to be integral to the tachycardia. Such sites are attractive ablation targets because they are composed of relatively few cells—hence, electrical silence on the surface ECG in diastole—and are thus more easily eliminated by the small amount of damage effected by a typical application of RF energy than other areas might be. Focal ablation of these sites can then be performed, but often tachycardia can still be initiated (usually at a slower rate) or recurs after the procedure. Because these sites are typically located at a relatively narrow zone between the ends of previous scars, surgical incisions, or ablation lines and another

FIGURE 35-9 ATs. In both panels the interval from the end of one P wave to the beginning of the next (atrial diastole) is in gray. A dashed line denotes onset of the P wave during tachycardia. **A**, Focal AT arising in the right atrium. Two tachycardia complexes are shown; the earliest site found (Abl_{dist}, at which ablation eliminated the tachycardia) is shown as a multicomponent recording that starts only approximately 40 milliseconds before onset of the P wave. The unipolar recording (Abl_{uni-d}) has a deep negative deflection (indicating propagation away from the electrode). The activation sequence of recordings is very different from that during sinus rhythm, in which the right atrial (RA) recording is at the onset of the P wave. **B**, Macroreentrant AT in a patient who had undergone repair of an atrial septal defect years earlier. The ablation catheter is in the posterior right atrium, where a fragmented signal (between arrows) is recorded that almost fills atrial diastole. Ablation at this site terminated the tachycardia. Recording was done as in previous figures.

FIGURE 35-11 Reentrant AT. **Left**, An electroanatomic activation map of the right atrium is shown in a patient with a previous right atrial incision for closure of an atrial septal defect. Scar is shown as gray areas; arrows depict a double loop of reentry around scars with a common diastolic pathway between scars. The color bar at center shows progression of activation times during AT (from red through green, blue, and purple). The tachycardia cycle length (350 milliseconds) is almost entirely represented in the range of colors. **Right**, Red dots are ablation sites connecting scars (transecting diastolic pathway) and connecting one scar to the inferior vena cava (IVC) to preclude reentry around all barriers. His = His bundle; SVC = superior vena cava; TV = tricuspid valve.

nonconducting barrier (e.g., another scar, caval orifice, valve annulus), another technique is to make a line of ablative lesions from the end of the scar to the nearest electrical barrier. Reentry can thereby be prevented. This technique is analogous to that used in curing atrial flutter (see later). Because these patients frequently have extensive atrial disease with islands of scar that could serve as barriers for additional ATs, specialized mapping techniques may be needed to locate these regions and preemptively connect them with ablative lesions to prevent future AT episodes.

Indications

Catheter ablation for ATs should be considered in patients who have recurrent episodes of symptomatic sustained ATs that are drug resistant or who are drug intolerant or do not desire long-term drug treatment.

Results

Success rates for ablation of focal AT range from 80% to 95%, largely depending on the ability to induce episodes at EPS; when episodes can be initiated with pacing, isoproterenol, or other means, the AT can usually be ablated. Reentrant ATs, although more readily induced by an EPS, are often more difficult to eliminate completely; initial success rates are high (90%), but recurrences are seen in up to 20% of patients and necessitate drug therapy or another ablation procedure. Complications, which occur in 1% to 2% of patients, include phrenic nerve damage, cardiac tamponade, and heart block (with rare perinodal ATs).

Radiofrequency Catheter Ablation of Atrial Flutter. Atrial flutter may be defined electrocardiographically (most typically, negative sawtooth waves in leads II, III, and aVF at a rate of approximately 300 beats/min) or electrophysiologically (a rapid, organized macroreentrant AT, the circuit for which is anatomically determined). Understanding of the reentrant pathway in all forms of atrial flutter is essential for development of an ablation strategy (see Chapter 37). Reentry in the right atrium, with the left atrium passively activated, constitutes the mechanism of the typical electrocardiographic variety of atrial flutter, with caudocranial activation along the right atrial septum and craniocaudal activation of the right atrial free wall

(Fig. 35-12A). Ablating tissue in a line between any two anatomic barriers that transects a portion of the circuit necessary for perpetuation of reentry can be curative. Typically, this is across the isthmus of atrial tissue between the inferior vena caval orifice and the tricuspid annulus (the cavotricuspid isthmus), a relatively narrow point in the circuit. Successful ablation can be accomplished at the point where the advancing flutter wave front enters this zone in the low inferolateral right atrium, near the exit of this zone at the inferomedial right atrium, or in between these sites. Locations for RF delivery can be guided anatomically or electrophysiologically. Less commonly, the direction of wave front propagation in this large right atrial circuit is reversed ("clockwise" flutter proceeding cephalad up the right atrial free wall and caudad down the septum with upright flutter waves in the inferior leads; Fig. 35-12A, right panel). This arrhythmia, which has been called atypical atrial flutter, can also be ablated by the same techniques as used for more typical atrial flutter. These two arrhythmias constitute cavotricuspid isthmus-dependent flutter and are distinct from other rapid atrial arrhythmias that may have a similar appearance on the ECG but use different (and often multiple) circuits in other parts of the right or left atrium. Ablation can be more difficult in these cases, which often occur in the setting of advanced lung disease or previous cardiac surgery or ablation. A common theme in these complex reentrant arrhythmias is the presence of an anatomically determined zone of inexcitability around which an electrical wave front can circulate. Specialized mapping tools and skills are necessary to achieve successful ablation in these cases.

In patients with atrial fibrillation, an antiarrhythmic drug can slow intra-atrial conduction to such an extent that atrial flutter results and fibrillation is no longer observed. In some of these patients, ablation of atrial flutter and having them continue to take the antiarrhythmic drug can prevent recurrences of these atrial arrhythmias.

The endpoint of atrial flutter ablation procedures was initially termination of atrial flutter, with RF application accompanied by noninducibility of the arrhythmia. However, with use of these criteria, up to 30% of patients had recurrent flutter because of lack of complete and permanent conduction block in the cavotricuspid isthmus. In the last several years the endpoint of ablation has changed to ensuring a line of bidirectional block in this region by pacing from opposite sides of the isthmus (Fig. 35-12B) or the use of other techniques. With use of these criteria, recurrence rates have fallen to less than 5%.

Indications

Candidates for RF catheter ablation include patients with recurrent episodes of atrial flutter that are drug resistant, those who are drug intolerant, and those who do not desire long-term drug therapy. Many patients who undergo atrial fibrillation ablation (see Chapter 38) also have episodes of flutter during the procedure that can be treated by ablation of the cavotricuspid isthmus at the same setting.

Results

Regardless of circuit location, atrial flutter can be ablated successfully in more than 90% of cases, although patients with complex right or left atrial flutter require more extensive and complex procedures. Recurrence rates are lower than 5% except in patients with extensive atrial disease, in whom new circuits can develop over time as new areas of conduction delay and block form. Complications are rare and include inadvertent heart block and phrenic nerve paralysis.

Ablation and Modification of Atrioventricular Conduction for Atrial Tachyarrhythmias

In some patients who have rapid ventricular rates despite optimal drug therapy during complex atrial tachyarrhythmias that are less amenable to ablation, RF ablation can be used to eliminate or to modify AV conduction and control the ventricular rates. To achieve this, a catheter is placed across the tricuspid valve and positioned to record a small His bundle electrogram associated with a large atrial electrogram. RF energy is applied until complete AV block has been achieved and is continued for an additional 30 to 60 seconds (Fig. 35-13). If no change in AV conduction is observed after 15 seconds of RF ablation despite good contact, the catheter is repositioned and the attempt repeated. In occasional patients, attempts at RF ablation via this right-sided heart approach fail to achieve heart block. These

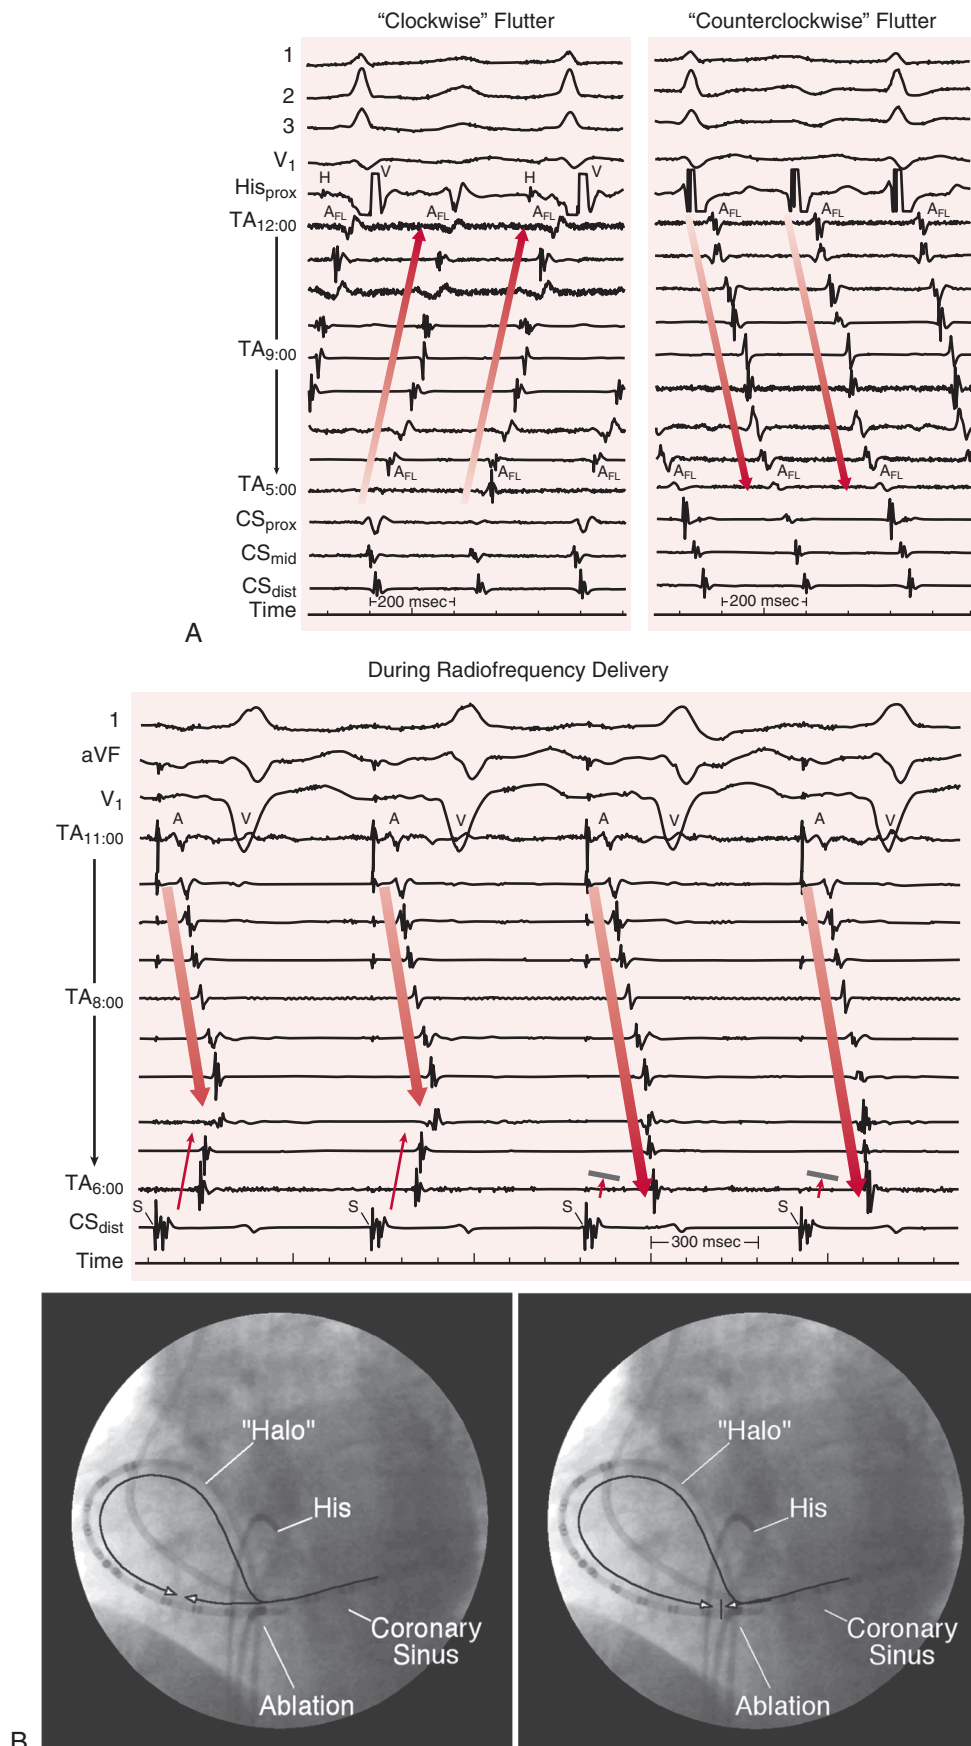

FIGURE 35-12 A, Two forms of atrial flutter in the same patient are shown. A halo catheter with 10 electrode pairs is situated on the atrial side of the tricuspid annulus (TA), with recording sites displayed from the top of the annulus (12:00) to the inferomedial aspect (5:00), as shown in the fluoroscopic views in **B**. On the **left**, the wave front of atrial activation proceeds in a clockwise fashion (arrows) along the annulus, whereas on the **right**, the direction of propagation is the reverse. **B**, Ablation of the isthmus of atrial tissue between the tricuspid annulus and the inferior vena caval orifice for cure of atrial flutter. Recordings are displayed from the multipolar catheter around much of the circumference of the tricuspid annulus (see the left anterior oblique fluoroscopic images). Ablation of this isthmus is performed during coronary sinus pacing. In the two beats on the **left**, atrial conduction proceeds in two directions around the tricuspid annulus, as indicated by arrows and recorded along the halo catheter. In the two beats on the **right**, ablation has interrupted conduction in the floor of the right atrium, thereby eliminating one path for transmission along the tricuspid annulus. The halo catheter now records conduction, proceeding all the way around the annulus. This finding demonstrates a unidirectional block in the isthmus; block in the other direction may be demonstrated by pacing from one of the halo electrodes and observing a similar lack of isthmus conduction. (The bundle of His recording in the **right** panel is lost because of catheter movement.)

FIGURE 35-13 AV nodal ablation for rate control of atrial fibrillation (AF). The ECG shows rapidly conducted AF; application of RF energy (arrow) results in complete AV block within seconds, followed by a ventricular paced complex.

patients can undergo an attempt from the left ventricle with a catheter positioned along the posterior interventricular septum, just beneath the aortic valve, to record a large His bundle electrogram. Energy is applied between the catheter electrode and skin patch or between catheters in the left and right ventricles. Success rates currently approach 100%, with AV conduction recurring in less than 5% of cases. Improved left ventricular function can result from control of the ventricular rate during atrial fibrillation and withdrawal of rate-controlling medications with negative inotropic action. Permanent ventricular or AV pacing is required after ablation. With continuing advances in direct ablation of complex atrial arrhythmias, AV nodal ablation is less commonly used currently.

In some cases the AV junction can be modified to slow the ventricular rate without producing a complete AV block by ablation in the region of the slow pathway, as described in connection with AV node modification for AV node reentry. Initial success rates for slowing of the ventricular response are good; however, long-term results are less consistent. Some patients have a gradual increase in the ventricular rate to almost preablation levels, whereas late complete heart block may occur in others. Nonetheless, this procedure can be tried before producing a complete AV block.

Indications

Ablation and modification of AV conduction can be considered in the following cases: (1) patients with symptomatic atrial tachyarrhythmias who have inadequately controlled ventricular rates unless primary ablation of the atrial tachyarrhythmia is possible (especially when a permanent pacemaker is already present for treatment of bradycardia-tachycardia syndrome); (2) similar patients when drugs are not tolerated or patients do not wish to take them, even though the ventricular rate can be controlled; (3) patients with symptomatic, nonparoxysmal junctional tachycardia that is drug resistant or in whom drugs are not tolerated or are not desired; (4) patients resuscitated from sudden cardiac death related to atrial flutter or atrial fibrillation with a rapid ventricular response in the absence of an accessory pathway; and (5) patients with a dual-chamber pacemaker and a pacemaker-mediated tachycardia that cannot be treated effectively by drugs or by reprogramming of the pacemaker. The last three situations are rarely encountered.

Results

As noted before, successful interruption of AV conduction can be achieved in almost all cases; recurrent conduction is observed in less than 5%. Significant complications occur in 1% to 2%. In early studies, up to 4% of patients had an episode of sudden death after AV junction ablation despite adequate pacemaker function, presumably because

of relative bradycardia after long periods of rapid ventricular rates serving as the setting for repolarization-related ventricular arrhythmias. Since then, backup pacing rates are set to 80 to 90/min for the first 1 to 3 months after ablation in most cases, which has almost entirely eliminated this problem. Improvements in quality-of-life indices, as well as in cost-effectiveness, have been demonstrated for this procedure.

Radiofrequency Catheter Ablation of Atrial Fibrillation. See [Chapters 37 and 38](#).

Radiofrequency Catheter Ablation of Ventricular Tachycardia

In general, the success rate for ablation of VTs is slightly lower than that for AV node reentry or AV reentry. This lower success rate may be related to the fact that this procedure is often a last resort in patients with drug-resistant VT and extensive structural heart disease, but it is also related to more difficult mapping in the ventricles. Furthermore, in the ideal case, induction of the VT must be reproducible, with uniform QRS morphology from beat to beat, and VT must be sustained and hemodynamically stable so that the patient can tolerate the VT long enough during the procedure to undergo the extensive mapping necessary to localize optimal ablation target sites. Patients with several electrocardiographically distinct, uniform morphologies of VT can still be candidates for ablation because in many cases a common reentrant pathway is shared by two or more VT morphologies. Also, the target for ablation must be fairly circumscribed and preferably endocardially situated, although cases of successful ablation only from the epicardial aspect have become more common. Very rapid VT, polymorphic VT, and infrequent, nonsustained episodes are less well suited to this form of therapy at this time (see later).

Location and Ablation. RF catheter ablation of VT can be divided into idiopathic VT, which occurs in patients with essentially structurally normal hearts; VT that occurs in various disease settings but without coronary artery disease; and VT in patients with coronary artery disease and usually previous myocardial infarction. In the first group, VTs can arise in either ventricle. Right ventricular tachycardias most commonly originate in the outflow tract and have a characteristic left bundle branch block–like, inferior axis morphology (see [Chapter 37](#)); less often, VTs arise in the inflow tract or free wall. Initiation of tachycardia can often be facilitated by catecholamines. Most left VTs are septal in origin and have a characteristic QRS configuration (i.e., right bundle branch block, superior axis); other VTs occur less commonly and arise from different areas of the left ventricle, including the left ventricular outflow tract and the aortic sinuses of Valsalva, and are similar in electrocardiographic appearance and clinical behavior to

FIGURE 35-14 VT and pace mapping. All 12 surface ECG leads are shown, along with intracardiac recordings during VT. The Abl₁₋₂ recording shows a small deflection occurring early in electrical diastole (arrowhead) 110 milliseconds before onset of the QRS (dashed line). In the **right panel**, pacing is performed from this site. This produces an identical QRS complex in each lead, with a stimulus-QRS onset interval similar to the electrogram-QRS onset interval during VT. Ablation at this site eliminated VT in 2 seconds. RVOT = right ventricular outflow tract.

those arising in the right ventricular outflow tract. Abnormal patterns of sympathetic innervation can be present in some. VTs in abnormal hearts without coronary artery disease can be the result of either intramyocardial or bundle branch reentry (see Chapter 37), most typically observed in patients with dilated cardiomyopathy or as a focal process. Epicardial foci and circuits are more common in this than in other groups. In patients with bundle branch reentry, ablation of the right bundle branch eliminates the tachycardia. VT can occur in patients with right ventricular dysplasia (see Chapter 32), sarcoidosis, Chagas disease, hypertrophic cardiomyopathy (see Chapter 66), and a host of other noncoronary disease states.

Activation mapping and pace mapping are effective in patients with idiopathic VTs to locate the site of origin of the VT. In activation mapping, the timing of endocardial electrograms sampled by the mapping catheter is compared with the onset of the surface QRS complex. Sites that are activated 20 to 40 milliseconds before onset of the surface QRS are near the origin of the VT (Fig. 35-14; also see Fig. 34-12). In idiopathic VT, ablation at a site at which the unipolar electrogram shows a QS complex may yield greater success than if an rS potential is observed (Fig. 35-15). Pace mapping involves stimulation of various ventricular sites to produce a QRS contour that duplicates the QRS contour of the spontaneous VT, thus establishing the apparent site of origin of the arrhythmia (see Fig. 35-14). This technique is limited by several methodologic problems but may be useful when the tachycardia cannot be initiated and when a 12-lead ECG has been obtained during the spontaneous VT. Presystolic Purkinje potentials, as well as very low-amplitude mid-diastolic signals, can be recorded during VT from sites at which ablation cures VT in most patients with left ventricular VTs that have a right bundle branch block superior axis. Localization of optimal ablation sites for VT in patients with coronary artery disease and previous infarction can be more challenging than in

patients with structurally normal hearts because of the altered anatomy and electrophysiology. Pace mapping has even lower sensitivity and specificity than for idiopathic VT. Furthermore, reentry circuits can sometimes be large and resistant to the relatively small lesions produced by RF catheter ablation in scarred endocardium.

In scar-based VT (e.g., after infarction, cardiomyopathies), finding of a protected region of diastolic activation used as a critical part of the reentrant circuit is desirable because ablation at this site has a good chance of eliminating the tachycardia (Fig. 35-16). As a result of the extensive derangement in electrophysiology caused by the previous damage (e.g., infarct, myopathy), many areas of the ventricle may have diastolic activation but may not be relevant to perpetuation of the VT. These “bystander sites” make activation mapping more difficult. Pacing techniques such as entrainment can be used to test whether a site is actually part of a circuit or is a bystander. Entrainment involves pacing for several seconds during a tachycardia at a rate slightly faster than the VT rate; after pacing is stopped and the same tachycardia resumes, the timing of the first complex relative to the last paced beat is an indicator of how close the pacing site is to a part of the VT circuit. During entrainment, part of the ventricle is activated by the paced wave front and part by the VT wave front being forced to exit earlier than it ordinarily would, thereby resulting in a fusion complex on the ECG. Pacing from within a critical portion of the circuit itself produces an exact QRS match with the VT; fusion

occurs only within the circuit and is “concealed” from being discerned on the surface ECG. Sites with a low-amplitude, isolated, mid-diastolic potential that cannot be dissociated from the tachycardia by pacing perturbations, at which entrainment with concealed fusion can be demonstrated, are highly likely to be successful ablation sites.

In a significant proportion of patients with VT and structural heart disease, activation mapping and entrainment cannot be performed because of poor hemodynamic tolerance of the arrhythmia or inability to initiate sustained tachycardia during an EPS. In these situations, additional methods can be used that are categorized as substrate mapping, in which areas of low electrical voltage or from which very delayed potentials are recorded during sinus rhythm or at which pacing closely replicates a known VT 12-lead ECG morphology (pace mapping) are targeted for ablation without needing any mapping during VT (Fig. 35-17). These methods have yielded very good results in many cases. In other cases, hemodynamic support in the form of catecholamine infusion, intra-aortic balloon counterpulsation, or a percutaneous temporary ventricular assist device or extracorporeal membrane oxygenation has been used to facilitate mapping during VT.²⁶

In patients without structural heart disease, only a single VT is usually present, and catheter ablation of that VT is most often curative. In patients with extensive structural heart disease, especially those with previous myocardial infarction, multiple VTs are usually present. Catheter ablation of a single VT in such patients may be only palliative and not eliminate the need for further antiarrhythmic therapy. The genesis of multiple tachycardia morphologies is not clear, although in some cases they are merely different manifestations of one circuit (e.g., different directions of wave front propagation or exit to the ventricle as a whole), and ablation of one may prevent recurrence of others. The presence of multiple VT morphologies contributes

FIGURE 35-15 Recordings from unsuccessful and successful ablation sites in a patient with idiopathic VT arising in the inferior right ventricular wall. In the recordings from the unsuccessful ablation site, the unipolar signal (arrowhead) has a small r wave, which indicates that a portion of the wave front from the focus of tachycardia is approaching the site from elsewhere. At the successful site, the unipolar recording has a QS configuration, thus indicating that all depolarization is emanating from this site. In each site the bipolar recording (Abl₁₋₂) occurs an identical 43 milliseconds before onset of the QRS (dashed lines).

FIGURE 35-16 RF ablation of postinfarction VT. The electrogram in the ablation recording (Abl₁₋₂, arrowhead) precedes onset of the QRS (dashed line) by 131 milliseconds. Ablation here (RF on) results in slight deceleration of VT before termination in 1.3 seconds. Temperature monitored from the catheter tip had just peaked ($\approx 70^{\circ}\text{C}$) at the time that VT terminated. Recording was done as in previous figures.

FIGURE 35-17 Mid-diastolic potentials during VT correlating with late potentials in sinus rhythm (SR). In **A**, VT is shown; diastole (from the end of one QRS complex to the beginning of the next) is shaded in gray. In the Abl_{dist} recording, a small, sharp signal is seen in mid-diastole that corresponds to a protected corridor of propagation. After termination of VT with pacing, recording at the same location shows a delayed ("late") potential in SR with tracked ventricular pacing (black arrows; the dashed line denotes the end of the QRS complex). Ablation here eliminated the late potential (white arrows), as well as inducible VT. A = atrial recording; S = stimulus artifact.

FIGURE 35-18 "Focal VF." Recordings are shown from a patient with multiple episodes of VF in a day; a sinus rhythm complex, during which a Purkinje potential (P) is recorded from the Abl electrode, is followed by a premature complex from that site that is preceded by sharp Purkinje spikes (arrows) that continue to precede subsequent complexes of polymorphic VT that degenerated to VF. Ablation at this site eliminated recurrent episodes of VF.

to the difficulties in mapping and ablation of VT in these patients because pacing techniques used to validate recordings at potential sites of ablation may result in a change in morphology to another VT that does not arise in the same region.

After ablation of VT, ventricular stimulation is repeated to assess efficacy. In some cases, rapid polymorphic VT or VF is initiated. The clinical significance of these arrhythmias is unclear, but some evidence has suggested that they have a low likelihood of spontaneous occurrence during follow-up.

As noted earlier, most cases of polymorphic VT and VF are not currently amenable to ablation because of hemodynamic instability and beat-to-beat changes in activation sequence. However, some cases appear to have a focal source (similar to the focal sources of atrial fibrillation), and if the focus can be identified and ablated, further arrhythmia episodes can be prevented. In such cases, repeated episodes of arrhythmia have constant electrocardiographic features of the initiating beat or beats, thus suggesting a consistent source, which may be in either ventricle. The electrogram at sites of successful ablation often has very sharp presystolic potentials reminiscent of Purkinje potentials, with a 50- to 100-millisecond delay until onset of the QRS (Fig. 35-18).²⁷

Indications

Patients considered for RF catheter ablation of VT in the absence of structural heart disease are those with symptomatic, sustained monomorphic VT when the tachycardia is drug resistant, when the patient

is drug intolerant, or when the patient does not desire long-term drug therapy. Patients with structural heart disease who are candidates for ablation include those with bundle branch reentrant VT and those with sustained monomorphic VT and an ICD who are receiving multiple shocks not manageable by reprogramming or concomitant drug therapy. On occasion, nonsustained VT or even severely symptomatic PVCs require RF catheter ablation. In some of these cases, in which the ventricular ectopy occurs frequently, significant left ventricular systolic dysfunction has occurred (presumably similar to tachycardia-related cardiomyopathy). After successful ablation, ventricular function may improve significantly or even normalize.

Results

In patients with structurally normal hearts, the success rate of VT ablation is approximately 85%.²⁸ In patients with postinfarction VT, more than 70% no longer have recurrences of VT after the ablation procedure despite inducibility of rapid VT or VF (only ~30% of patients will have no inducible ventricular arrhythmia of any type and no spontaneous recurrences). Almost all these patients have an ICD, regardless of outcome. Significant complications occur in up to 3%, including vascular damage, heart block, worsening of heart failure, cardiac tamponade, stroke, and valve damage; death is rare but can occur in patients with severe coronary artery disease and/or systolic dysfunction.

New Mapping and Ablation Technologies

Multielectrode Mapping Systems. As noted earlier, many limitations of ablation are related to inadequate mapping. These problems include having only isolated premature complexes during the EPS as opposed to sustained tachycardias (in idiopathic AT and VT), nonsustained episodes of VT, poor hemodynamic tolerance of VT, and multiple VT morphologies. Standard mapping techniques sample single sites sequentially and are poorly suited to these situations. New mapping systems are available that enable sampling of many sites simultaneously and incorporate sophisticated computer algorithms for analysis and display of global maps. These mapping systems use various technologies ranging from multiple electrodes situated on each of several splines of a basket catheter (see Fig. 34-16), to the use of low-intensity electrical or magnetic fields to localize the tip of the catheter in the heart and record and plot activation times on a contour map of the chamber, to the use of complex mathematics to compute "virtual" electrograms recorded from a mesh electrode situated in the middle of a chamber cavity or on the body surface. Some of these systems are capable of generating activation maps of an entire chamber by using only one cardiac complex, an obvious advantage in patients with only rare premature complexes, nonsustained arrhythmias, or poor hemodynamic tolerance of sustained arrhythmias.

Epicardial Catheter Mapping. Although most VTs can be ablated from the endocardium, occasional cases are resistant to this therapy. In many of these cases, epicardial ablation may be successful. It is often needed in VT attributable to cardiomyopathy but less frequently in postinfarction patients and those without structural heart disease.

For gaining access to the pericardial space for epicardial mapping and ablation, a long spinal anesthesia needle is introduced from a subxiphoid approach under fluoroscopic guidance. As the pericardium is approached, a small amount of radiocontrast agent is injected. If the tip of the needle is still outside the pericardium, the dye stays where it is injected; when the pericardial space has been entered, the dye disperses and outlines the heart. A guidewire is introduced through the needle and a standard vascular introducer sheath is exchanged over the wire. The pericardial space is then accessible for a mapping/ablation catheter. The usual mapping techniques can then be applied. When a site is selected for possible ablation, coronary arteriography is usually warranted to avoid delivery of RF energy near a coronary artery. This is less important in cases of postinfarction VT because the VT substrate is typically in a region of previous transmural infarction. The technique can be used for patients who have previously undergone cardiac surgery, although adhesions may obliterate portions of the pericardial space; on occasion, a small subxiphoid incision is needed for better access and visualization of the space. The most frequent complication of epicardial mapping is pericarditis related to the ablation; cardiac tamponade is rare.

Chemical Ablation. Chemical ablation of an area of myocardium involved in a tachycardia with alcohol or phenol has been used to create AV block in patients not responding to catheter ablation and to eliminate AT and VT. Recurrences of tachycardia several days after apparently successful ablation are common. Excessive myocardial necrosis is the major complication, and alcohol ablation should be considered only when other ablative approaches fail or cannot be done.

Several other mapping/imaging techniques have been developed recently, including integration of a previously obtained computed tomography or magnetic resonance imaging study into computerized mapping systems and use of intracardiac ultrasound to construct a facsimile of the intracardiac anatomy in any chamber during ablation procedures to guide placement of anatomic ablation and reduce fluoroscopic exposure, use of algorithms to select complex fractionated atrial electrograms for ablation in patients with atrial fibrillation, and algorithms to assess the fidelity of pace maps with native tachycardia complexes.

SURGICAL THERAPY FOR TACHYARRHYTHMIAS

The objectives of a surgical approach to treatment of a tachycardia are to excise, isolate, or interrupt tissue in the heart critical for initiation, maintenance, or propagation of the tachycardia while preserving or even improving myocardial function. In addition to a direct surgical approach to the arrhythmia, indirect approaches such as

aneurysmectomy, coronary artery bypass grafting, and relief of valvular regurgitation or stenosis can be useful in selected patients by improving cardiac hemodynamics and myocardial blood supply. Cardiac sympathectomy alters adrenergic influences on the heart and has been effective in some patients, particularly those who have recurrent VT with long-QT syndrome despite beta blockade and catecholaminergic polymorphic VT.

Supraventricular Tachycardias

Surgical procedures exist for patients (adults and children) with AT, atrial flutter and fibrillation (see Chapter 38), AV node reentry, and AV reentry (Fig. 35-19). RF catheter ablation adequately treats most of these patients and thus has replaced direct surgical intervention, except for the occasional patient in whom RF catheter ablation fails or who is undergoing concomitant cardiovascular surgery. In some cases, a prior attempt at RF catheter ablation complicates surgery by obliterating the normal tissue planes that exist in the AV groove of the heart or by rendering tissues friable. On occasion, patients with ATs have multiple foci that require surgical intervention. Several surgical procedures have been developed to treat atrial fibrillation; these are reviewed in Chapter 38.

Ventricular Tachycardia

In contrast to patients with supraventricular arrhythmias, candidates for surgical therapy for ventricular arrhythmias often have severe left ventricular dysfunction, generally the result of coronary artery disease. The cause of the underlying heart disease influences the type of surgery performed. Candidates are patients with drug-resistant, symptomatic, recurrent ventricular tachyarrhythmias who ideally have a segmental wall motion abnormality (scar or aneurysm) with preserved residual left ventricular function, have not benefited from previous attempts at catheter ablation, or are not candidates for catheter ablation because of hemodynamic instability during VT or the presence of left ventricular thrombi (precluding endocardial catheter ablation). Poorer surgical results are obtained in patients with nonischemic cardiomyopathy.

Ischemic Heart Disease

In almost all patients who have VT associated with ischemic heart disease, the arrhythmia, regardless of its configuration on the surface ECG, arises in the left ventricle or on the left ventricular side of the interventricular septum. The electrocardiographic contour of the VT can change from a right bundle branch block to a left bundle branch block pattern without a change in the site of earliest diastolic activation, thus suggesting that the location of the circuit within the left

FIGURE 35-19 Schematic diagram showing the two approaches for surgical interruption of an accessory pathway. **Left**, Left AV groove and its vascular contents the coronary sinus (CS) and circumflex coronary artery (CA). Multiple accessory pathways (APs) course through the fat pad. **Middle**, Approach for epicardial dissection. **Right**, Endocardial dissection. Both approaches clear out the fat pad and interrupt any accessory pathways. (From Zipes DP: *Cardiac electrophysiology: Promises and contributions*. J Am Coll Cardiol 13:1329, 1989. Reprinted by permission of the American College of Cardiology.)

FIGURE 35-20 Schematic diagram showing surgical procedures for the treatment of postinfarction VT with a left ventricular aneurysm. A damaged left ventricle is depicted as opened along the lateral wall and showing the septum and papillary muscles. The tachycardia circuit (**upper left**) takes a meandering course near the point where the aneurysm meets normal myocardium and at times is superficial (purple lines) and at other times is coursing deeper (green lines). Simple aneurysmectomy that leaves a portion of the aneurysm for suturing often misses the circuit and thus does not cure the arrhythmia. By subendocardial resection, a layer of endocardium and subjacent tissue is removed, including at least some of the tachycardia circuit. Such resection results in elimination of the tachycardia. Encircling endocardial ventriculotomy attempts to isolate the circuit electrically without removal of tissue, but it probably actually works by incising portions of the circuit. Cryoablation can be used to encircle the infarct zone or in combination with resection of damaged tissue too deep in the wall to be resected safely.

ventricle remains the same, often near the septum, but its exit pathway is altered.

Indirect surgical approaches, including cardiothoracic sympathectomy, coronary artery revascularization, and ventricular aneurysm or infarct resection with or without coronary artery bypass grafting, have been successful in no more than 20% to 30% of reported cases. Coronary artery bypass grafting as a primary therapeutic approach has generally been successful only in patients who experience rapid VT because of severe ischemia, as well as in patients with ischemia-related VF, but it can sometimes be useful in patients with coronary disease resuscitated from sudden death who have no inducible arrhythmias at EPS. These patients generally have a clear relationship between episodes of ventricular arrhythmia and immediately antecedent severe ischemia and have no evidence of infarction or minimal wall motion abnormalities but have preserved overall left ventricular function. Patients with sustained monomorphic VT or only polymorphic VT rarely have their arrhythmias affected by coronary bypass surgery, although it can reduce the frequency of the arrhythmic episodes in some patients and prevent new ischemic events.

Surgical Techniques. In general, two types of direct surgical procedures are used, resection and ablation (**Fig. 35-20**). The first direct surgical approach to VT was encircling endocardial ventriculotomy, which entails performing a transmural ventriculotomy to isolate areas of endocardial fibrosis that were recognized visually; this procedure is rarely used now. Another procedure, subendocardial resection, is based on data indicating that arrhythmias after myocardial infarction arise mostly at the subendocardial borders between normal and infarcted tissue. Subendocardial resection involves peeling off a 1- to 3-mm-thick layer of endocardium, often near the rim of an aneurysm, that has been demonstrated by mapping procedures to contain sites of mid-diastolic activation recorded during VT. Tachycardias arising from near the base of the papillary muscles are treated with a cryoprobe cooled to -70°C . Cryoablation can also be used to

isolate areas of the ventricle that cannot be resected and is often combined with resection. Lasers have also been used with good success, but the equipment is expensive and cumbersome.

Results. For ventricular tachyarrhythmias, operative mortality ranges from 5% to 10%; success, defined as the absence of recurrence of spontaneous ventricular arrhythmias, is achieved in 59% to 98% of patients. In experienced centers, operative mortality can be as low as 5% in stable patients undergoing elective procedures, with 85% to 95% of survivors being free of inducible or spontaneous ventricular tachyarrhythmias. Long-term recurrence rates range from 2% to 15% and correlate with results of the patient's postoperative electrophysiologic stimulation study. Operative survival is strongly influenced by the degree of left ventricular dysfunction.

Operative mortality for nonthoracotomy ICD implantation is far less than 1%, with an annual sudden cardiac death mortality rate of less than 2%. Because of the difference in operative survival and shorter hospital stay with ICD insertion than with direct surgery for VT and the success rates for catheter ablation in patients who have an ICD but experience frequent episodes of VT, few curative surgical procedures are now performed.

Electrophysiologic Studies

Preoperative Electrophysiologic Study. In patients for whom direct surgical therapy for VT is planned, a preoperative EPS is usually warranted. This study involves initiation of the VT and electrophysiologic mapping to localize the area to be resected, as is done with catheter ablation. Preoperative catheter mapping is contraindicated in patients with known left ventricular thrombi that might be dislodged by the mapping catheter.

Intraoperative Ventricular Mapping. Electrophysiologic mapping is also performed at the time of surgery, with the surgeon using a handheld probe or an electrode array coupled with computer techniques that instantaneously provide an overall activation map, cycle by cycle. The sequence of activation during VT can be plotted and the area of earliest activation determined. Resection or cryoablation of tissue from which these recordings are made usually cures the VT, thus indicating that they represent a critical portion of the reentrant circuit. When the earliest recordable endocardial electrical activity occurs less

than 30 milliseconds before onset of the QRS complex, the critical portions of the circuit may be in the interventricular septum or near the epicardium of the free wall. In some patients, intramural mapping using a plunge needle electrode can be useful. Most centers have used a strategy of "sequential" subendocardial resection in which VT is initiated, mapped, and ablated (resected or cryoablated) while the heart is warm and beating, and stimulation is repeated immediately. If VT can still be initiated, mapping and resection are also repeated until VT can no longer be initiated. Reentry around an inferior scar, with a critical diastolic pathway confined to an isthmus of ventricular muscle between the scar and mitral valve annulus, can be cured by cryoablation of this isthmus. Cure rates in this situation exceed 93%.

BACKGROUND: CARDIAC ELECTRICAL STIMULATION

Electrical therapy for cardiac arrhythmias includes low-voltage pacing pulses, which are used to treat bradycardia or to provide antitachycardia pacing (ATP) for termination of reentrant tachycardias, and high-voltage shock pulses, which are used to defibrillate atrial fibrillation (AF) or ventricular fibrillation (VF) or to cardiovert ventricular tachycardia (VT).

An applied electrical stimulus interacts with cardiac electrical activity via its resultant electrical field, which is proportional to the spatial derivative of the voltage applied (local rate of change with respect to the distance derivative). The response of the heart is mediated by the passive and active (ion channel) properties of cell membranes, by the properties of electrical connections between cardiac cells, and possibly by direct intracellular electrical effects.

Local and Global Effects of Cardiac Electrical Stimulation

Local. Cardiac pacing requires a local stimulus sufficient to depolarize (reduce the membrane potential of) local myocardium during diastole and initiate a self-propagating wave front of depolarization. To achieve this local effect, pacing pulses are delivered from electrodes with small surface areas (1 to 6 mm²). The local field strength required is approximately 1 V/cm. A stimulus that successfully stimulates local myocardium is said to capture it.

Bradycardia pacing requires that the stimulus capture fully excitable local myocardium during diastole. The stimulated wavefront then propagates to most or all of the myocardium, which is also fully excitable, thereby resulting in electrical depolarization of cells and resultant mechanical contraction. In contrast, ATP stimuli must interact with the specific reentrant circuit driving the tachycardia, which is generally remote from the site of pacing, and it must do so while most of the myocardium is refractory or relatively refractory. Thus the ATP stimulus must capture local myocardium during the relative refractory period, propagate to the reentry circuit through relatively refractory myocardium, enter the circuit during an excitable gap in refractoriness, and terminate the tachycardia by causing a bidirectional block (see [Chapter 33](#)). Stimulus strength for local capture by ATP is higher than

that for bradycardia pacing because ATP pulses are usually delivered to myocardium that is relatively refractory rather than fully excitable.

Global. In contrast to pacing, initiation and termination of AF or VF by shocks require global field effects. Defibrillation shocks are delivered from electrodes with large surface areas (400 to 800 mm² for transvenous electrodes, 35 to 70 cm² for subcutaneous or epicardial electrodes, and 75 to 100 cm² for transthoracic electrodes/patches) separated by 10 to 40 cm. The minimum global field strength required for ventricular defibrillation is 3 to 4 V/cm when using biphasic shocks and 5 to 6 V/cm when using monophasic shocks. Although the field strength required for defibrillation is only a few multiples of that needed for pacing, defibrillation requires that these field strengths be achieved throughout all (or almost all) of the ventricular myocardium, whereas pacing requires achieving it only locally, within a few millimeters of the tip electrode. This spatial difference in field requirements alone requires that defibrillation pulses contain approximately a million times as much energy as a pacing pulse. Additionally, the cardiac time constant (see later) is approximately 10 times longer for defibrillation than for pacing. Combining these two considerations, defibrillation pulses require approximately 10 million times more energy than pacing pulses do.

Principles of Bioelectrical Stimulation

Thresholds for Pacing and Defibrillation. A threshold stimulus is the minimum stimulus required to evoke a response. Stimuli weaker than the threshold never evoke a response, and stimuli stronger than the threshold always evoke a response. Thus the threshold for pacing is the minimum stimulus strength needed to depolarize local myocardium and to initiate a propagated response. Defibrillation is best described by a probability-of-success curve ([Fig. 36-1A](#)) rather than by a threshold.¹ Shock strength is plotted on the abscissa and probability of successful defibrillation on the ordinate. Because defibrillation is probabilistic, the same clinically relevant shock strength may either succeed or fail on successive attempts. Nevertheless, the term *defibrillation threshold* (DFT) is used as the minimum shock strength that results in defibrillation during testing. DFT testing refers to various methods that assess the efficacy of defibrillation by calculating a shock strength on the sloping portion of the curve based on successes and failures of a few shocks at different strengths. Thus these methods are based on limited, discrete sampling of a continuous statistical

distribution (Fig. 36-1B). Because repeated sampling of a probability distribution is likely to result in variations, repeated measurements of the DFT result in variation in measured values.

Waveforms. The waveform of an electrical pulse is the temporal pattern of its amplitude, measured by voltage (or current). Voltage is a critical parameter for pacing or defibrillation because it determines the electrical field that interacts with the heart. In general, current is linearly related to voltage by Ohm's law ($V = IR$, where V is voltage, I is current, and R is resistance). Waveform duration is critical because a pacing pulse or shock interacts with the heart for the duration of the waveform. Furthermore, the time course of the heart's response to a pacing or defibrillation pulse depends on time-dependent passive and active ion channel processes, collectively referred to as the membrane time constant (τ_m) of cardiac tissue (see Chapter 33). Thus the most easily measured electrical parameter relevant to pacing or defibrillation is voltage (or current) as a function of time. Although implantable cardioverter-defibrillator (ICD) shocks are often specified in terms of energy (joules), energy is not a direct determinant of defibrillation.

All pacing and defibrillation in implantable devices result from discharge of a capacitor. Thus they have a fixed leading-edge voltage and a trailing-edge voltage determined by the waveform duration and waveform time constant τ_w , which is defined as the product of the capacitance (C) and electrical resistance (R) of the pacing or defibrillation pathway (electrodes and tissue, $\tau_w = RC$). τ_w is the duration in which the capacitor delivers 86% of its stored energy. Because pacing waveforms are short pulses delivered through high-resistance pathways, they approximate constant-voltage pulses with a lower amplitude, longer duration after potentials of opposite polarity (Fig. e36-1A). Defibrillation pulses are high-voltage, capacitive-discharge, truncated exponential waveforms as shown in Figure e36-1B. Biphasic waveforms defibrillate more efficiently (lower voltage) than monophasic waveforms do (Fig. e36-1C). ICDs deliver

"single-capacitor" biphasic waveforms in which the initial voltage of the second phase equals the final voltage of the first phase because they can be generated by reversing the polarity of a single capacitor after the first phase is truncated and then continuing the discharge.

Strength-Duration Relationship. A plot of the stimulus strength required for pacing or the shock strength required for defibrillation as a function of pulse duration is known as a strength-duration curve (Fig. 36-2). The strength-duration curve can be approximated by an inverse exponential or hyperbolic function. The strength-duration curve is characterized by two parameters. The rheobase is the long-duration asymptote (essentially the lowest value), which is determined by properties of the lead system and electrode-myocardial interface.

The chronaxie is the duration at which the threshold is twice the rheobase amplitude. It may be considered an approximation of an aggregate membrane time constant for the myocardium. Clinically, the chronaxie is important for design of efficient pacemakers and ICDs because it relates to the waveform that paces or defibrillates with the lowest energy, and minimizing the energy required is an important consideration for the longevity and size of pacemaker and ICD generators. A waveform with a duration approximately equal to the chronaxie paces with the lowest energy. Presently, no comprehensive theory permits determining the waveform duration that defibrillates with lowest energy from first principles, but approximations and empiric data relate it to the chronaxie. For capacitive-discharge defibrillation waveforms, the duration (of the first phase of a biphasic waveform) that defibrillates with minimum energy may be considered intermediate between the optimal duration for response of the cell membrane (chronaxie or τ_m) and the optimal duration for the capacitor to deliver its charge (τ_w). Usually, τ_w exceeds τ_m , so phase 1 of transvenous biphasic waveforms exceeds the chronaxie by 25% to 75%.

Programming Strength, Duration, and Polarity of Pacing and Defibrillation Pulses. The durations of pacing and defibrillation pulses are optimized to achieve the desired physiologic result with the

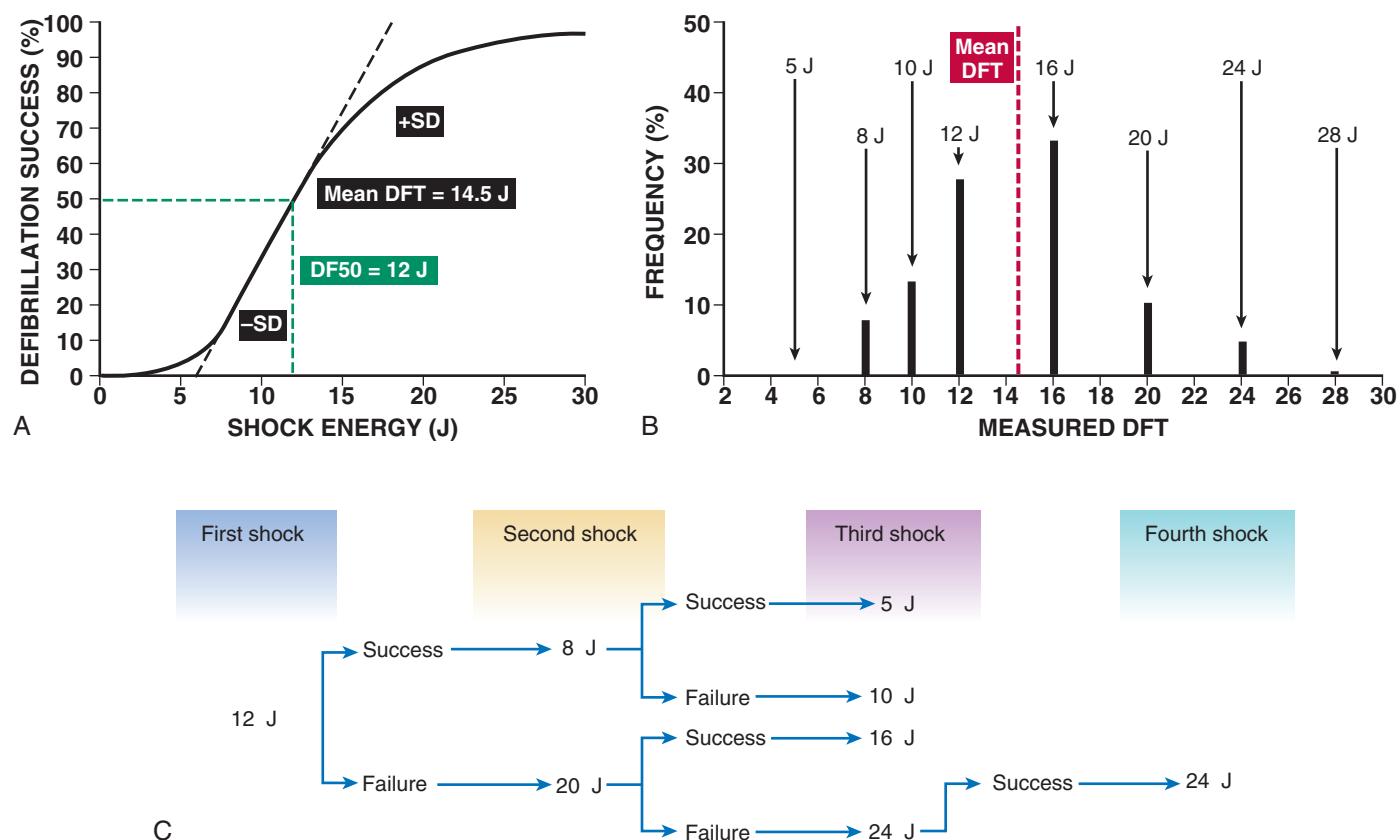

FIGURE 36-1 Relationship between the defibrillation probability-of-success curve (A) and measured DFT (B) during repeated testing in an individual patient by using the sequence of three or four test shocks shown in C. This sequence, known as a binary search protocol, starts at 12 J, the shock strength with a 50% probability of success (DF50). The process defined by the binary search protocol results in a single value, which the clinician records as the patient's "DFT." The right upper panel shows the statistical distribution of 50,000 simulated repetitions of this binary search DFT process applied to the defibrillation probability-of-success curve. Even for the most frequently measured DFT value (16 J), there is only about a one-third chance that repeating the process will yield the same result. The mean measured DFT (14.5 J) corresponds to DF68. However, 1 SD of measured DFTs extends from DF30 to DF87. (Modified from Smits K, Virag N: Impact of defibrillation test protocol and test repetition on the probability of meeting implant criteria. *Pacing Clin Electrophysiol* 34:1515, 2011.)

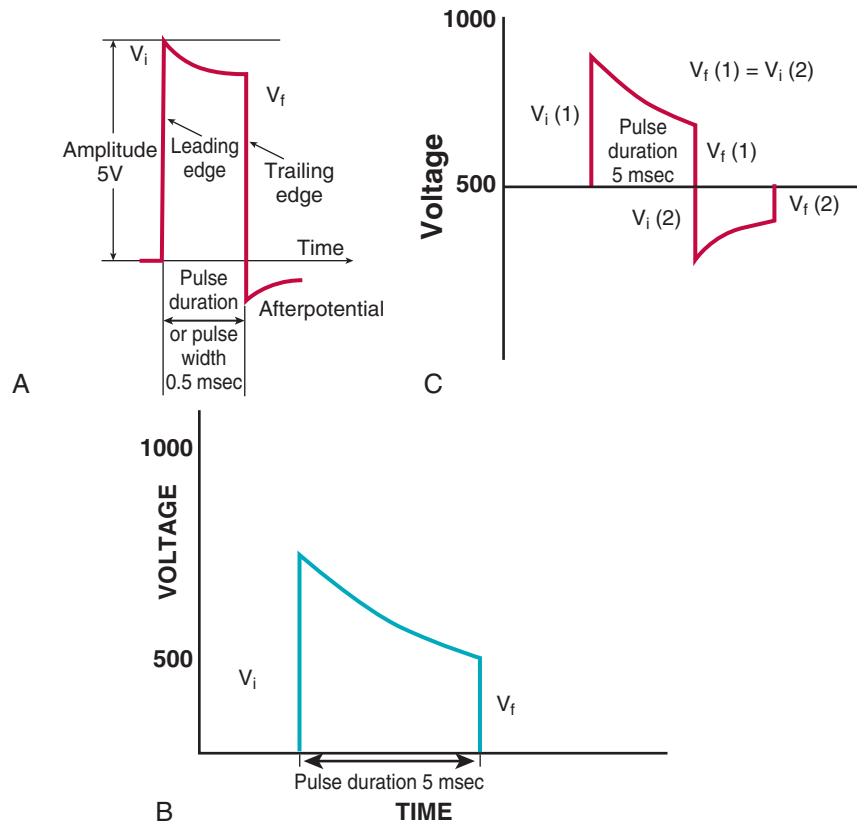

FIGURE e36-1 Pacing and defibrillation waveforms. All pacing and defibrillation waveforms in implantable devices have capacitive-discharge waveforms with a fixed leading-edge voltage and a trailing-edge voltage determined by the waveform duration and time constant τ_w . **A**, Pacing waveform. **B**, Monophasic truncated exponential waveform with initial voltage V_i and final voltage V_f . In comparison to the pacing waveform, the voltage is approximately 100 times greater and the duration is approximately 10 times greater. **C**, Biphasic truncated exponential waveform with initial voltage of the second phase, $V_i(2)$, equal to the final voltage of the first phase, $V_f(1)$.

FIGURE 36-2 Relationships among chronic ventricular strength-duration curves from a canine, expressed as potential (V), charge (μC), and energy (μJ). Rheobase is the threshold at an infinitely long pulse duration. Chronaxie is the pulse duration at twice the rheobase. (Reprinted from Stokes K, Bornzin G: *The electrode-biointerface stimulation*. In Barold SS [ed]: *Modern Cardiac Pacing*. Mount Kisco, NY, Futura, 1985, pp 33-77.)

minimum energy consumption from the device's battery. Typically, the voltage output for pacing is set at 1.5 to 2 times the threshold at pulse durations of 0.4 to 0.5 millisecond and at 1.5 to 2 times the pacing chronaxie of 0.2 to 0.3 millisecond. Lower safety margins may be programmed for pacemakers that determine capture automatically on a beat-to-beat basis. The shock strength for defibrillation is typically programmed near the ICD's maximum output of 750 to 900 V or 30 to 40 J with pulse durations of 3.5 to 6 milliseconds for the first phase of biphasic waveforms, longer than the defibrillation chronaxie of about 3 milliseconds but toward the short end of the range that permits the ICD to deliver the energy stored on the high-voltage capacitor.

At the long coupling intervals used for bradycardia pacing, the pacing threshold is lower if the negative electrode (cathode) is used for stimulation, but at short coupling intervals, which may initiate tachyarrhythmias, the stimulation threshold is lower for the positive electrode (anode). Thus cathodal pacing is preferred for bradycardia pacing to enhance the device's longevity and to minimize proarrhythmia. Anodal stimulation of the right ventricular defibrillation electrode is preferred for defibrillation, although polarity has little effect on the efficacy of defibrillation for presently used biphasic defibrillation waveforms.

Metabolic Effects on Pacing and Defibrillation Thresholds. The most clinically important metabolic abnormality is hyperkalemia, which raises pacing and defibrillation thresholds and alters sensing by causing conduction delays and local conduction block. Additionally, marked acidosis or alkalosis raises pacing thresholds but does not affect defibrillation thresholds. Profound hypothyroidism can also raise the pacing threshold.

Intracardiac Electrogram

An electrogram (EGM) displays the electrical potential difference between two points in space over time. The electrocardiogram (ECG), recorded from two electrodes on the body's surface, records electrical activity from the entire heart. In contrast, EGMs recorded from small endocardial or epicardial pacing electrodes record only local activity. Because EGMs record a difference in potential between two points, two electrodes are always required. However, in common use, the terms *unipolar* and *bipolar* refer to the number of intracardiac electrodes in the recording electrode pair. Unipolar EGMs are recorded between an electrode in the heart and a remote electrode, whereas bipolar EGMs are recorded between two intracardiac electrodes. Corresponding unipolar and bipolar terminology is applied to the electrodes used for pacing.

Unipolar EGMs are recorded between a small tip electrode in the heart and a large remote (indifferent) electrode, typically the metal housing of the pulse generator device, or the can. The location of the remote electrode has little effect on the cardiac EGM, but it may

record noncardiac potentials, such as pectoral myopotentials. Bipolar (true bipolar) EGMs are recorded between the tip and ring electrodes on a lead. Integrated bipolar EGMs are recorded between the tip of a right ventricular defibrillation lead and the large right ventricular coil. When compared with true bipolar electrodes (tip to ring), integrated bipolar EGMs have a wider field of view and thus are more likely to oversense nonphysiologic signals or physiologic signals that do not reflect local myocardial depolarization (Fig. 36-3A). Signals that do not originate in the local myocardium are called far-field signals. They include signals originating in a different cardiac chamber.

The typical amplitude of transvenous atrial and ventricular EGMs is in the range of 1.0 to 5 mV and 5 to 20 mV, respectively. The frequency content of ventricular and atrial EGMs is similar (5 to 50 Hz). T waves have a lower frequency (1 to 10 Hz), whereas most noncardiac myopotentials and electromagnetic interference have higher frequencies. This permits the use of electronic band pass filters to reduce sensing of signals that do not represent myocardial depolarization (oversensing) (Fig. 36-4).

Hemodynamics Related to Pacing Chronotropic Response

Heart rate and stroke volume are the two determinants of cardiac output, which increases fivefold to sixfold to meet the metabolic demands from rest to peak exercise. The ability of the heart rate to increase during exertion is termed *chronotropic competence*. It plays a particularly large role as exertion approaches its peak.

Atrioventricular Synchrony

Atrial filling of the left ventricle occurs throughout diastole as long as the mitral valve remains open, beginning with the early diastolic filling phase. At the end of diastole, immediately before the onset of systole, the atria contract, which results in a bolus of blood that contributes appreciably to ventricular stroke volume. Maximizing the atrial contribution to cardiac output requires optimal timing of electrical activation of the atria before the onset of ventricular contraction. The coordination of atrial and ventricular electrical activation and mechanical contraction is called atrioventricular (AV) synchrony. The presence of AV synchrony may increase cardiac output by 25% to 30%. Patients with impaired diastolic function or impaired systolic function are most dependent on atrial transport.

Any circumstance that prevents appropriate timing of atrial and ventricular contraction can result in impaired AV synchrony along with its hemodynamic consequences. The most hemodynamically disadvantageous AV timing relationship occurs during ventricular pacing with retrograde (ventriculoatrial [VA]) conduction, which results in reverse (VA) synchrony and atrial contraction while the AV valves are closed. Pacemaker syndrome can occur if retrograde conduction is present during single-chamber ventricular pacing or during dual-chamber pacing with loss of atrial pacing or with unreliable sensing. Patients with long PR intervals can exhibit several causes of impaired mechanical dyssynchrony (despite electrical synchrony), depending on the degree of PR prolongation. If the PR interval is extremely long such that the preceding P wave occurs during the preceding ventricular systole, atrial contraction occurs when the mitral valve is closed, a situation akin to ventricular pacing with retrograde conduction but without retrograde atrial activation. If the PR interval is slightly shorter, atrial contraction occurs after the mitral valve has opened but before much of the passive atrial contribution to ventricular filling has been completed. As a result, there may be diastolic mitral regurgitation because of backward flow from the left ventricle to the left atrium while the mitral valve remains open before ventricular systole has begun. If the PR interval is too short, the contribution of atrial contraction is insufficient because the mitral valve closes before atrial systole is complete. *Pacemaker syndrome* refers to the constellation of symptoms caused by loss of mechanical AV synchrony. As noted, it may occur with AV dissociation or with 1:1 AV association that results in an adverse sequence of ventricular and atrial contraction.

Studies have examined the clinical consequences of not having AV synchrony. In the MOST study, patients with sinus node disease were

FIGURE 36-3 Defibrillation and pacing lead design. **A**, Basic components of a passive fixation pacing lead: varieties of conductor construction. *Top panel*: Bipolar coaxial design with an inner multifilar coil surrounded by insulation (inner), an outer multifilar coil, and outer insulation. *Bottom panel*: Schematic of a passive fixation lead with identification of the electrode, insulation, conductor, and connector pin. **B**, True bipolar (*top*) and integrated bipolar (*bottom*) defibrillation leads. The true bipolar lead senses between the distal tip and the proximal ring, which are dedicated for pacing and sensing. True bipolar leads have a single coil. In contrast, integrated bipolar leads pace and sense between the tip and the distal coil. The distal coil is used for sensing, pacing, and defibrillation. Integrated bipolar leads also contain a second, proximal coil, which increases the lead surface area for defibrillation. Passive fixation (*top*) or active fixation (*bottom*) may be used with either lead design. ETFE = ethyltetrafluoroethylene; PTFE = polytetrafluoroethylene; SE = sensing electrode; SVC = superior vena cava.

randomly assigned to DDD versus VVI pacing. The study demonstrated a lower incidence of AF and heart failure in the DDD pacing arm.¹

Adverse Consequences of Right Ventricular Pacing

In patients with impaired AV conduction, DDD pacing delivers right ventricular pacing to ensure that the AV interval is in the physiologic range. However, right ventricular pacing results in intraventricular

asynchrony, which has adverse hemodynamic effects (see Chapter 26). In patients with underlying left ventricular dysfunction, right ventricular pacing increases the incidence of heart failure and AF.² Although no maximal PR interval has been established, some clinicians use a “cutoff” of approximately 350 to 400 milliseconds. In patients with intact AV conduction but a long PR interval, there may be a hemodynamic “trade-off” between having optimal AV timing and accepting the impaired hemodynamics of right ventricular pacing. Pacing algorithms to avoid unnecessary right ventricular pacing in patients with normal intraventricular conduction are discussed later under Pacing Modes.

INDICATIONS AND DEVICE SELECTION

The American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines for device-based therapy for cardiac rhythm abnormalities were updated in 2008.³ The Guidelines section of this chapter provides guidelines that apply to pacemakers and ICDs. Guidelines for cardiac resynchronization devices are presented in Chapter 26.

Indications: Pacemakers

The main indications for permanent pacing are to relieve or prevent symptomatic bradycardia. They are supported by strong expert consensus but were developed before the era of randomized controlled trials. The strongest indications are related to relief of symptoms confirmed to be caused by bradycardia. Pacing is also indicated for patients who have documented asymptomatic bradycardia and for those with symptoms consistent with bradycardia but no documentation of bradycardia during symptoms, provided that alternative causes of the symptoms have been excluded and the symptoms are sufficiently serious. Pacing is indicated to prevent symptomatic bradycardia in asymptomatic patients if the risk for rapid progression to serious symptoms is high. This indication is applied most commonly to patients with advanced disease of

the His-Purkinje system who are at risk for abrupt, high-grade AV block without an adequate escape rhythm.

Indications: Implantable Cardioverter-Defibrillators

ICDs are indicated for prevention of sudden death from VT/VF either as “secondary prevention” in patients who have been resuscitated

FIGURE 36-4 Electromagnetic frequency spectrum of intracardiac events. PVC = premature ventricular contraction.

from sustained VT/VF or as “primary prevention” in patients without arrhythmic symptoms who are judged to be at sufficient risk for VT/VF.

ICDs are the treatment of choice for secondary prevention of VT/VF, provided that patients remain at risk for recurrence of VT/VF and have sufficient life expectancy and quality of life to justify implantation. The strong consensus on the use of ICDs for secondary prevention is based on multiple, randomized controlled trials that compared antiarrhythmic drugs with ICDs, including the AVID (Antiarrhythmics Versus Implantable Defibrillators) study.⁴

Presently, more than 80% of ICDs are implanted for primary prevention. The MADIT II⁵ and SCD-HeFT⁶ randomized controlled trials demonstrated absolute mortality reductions of 5% to 7% over a period of 2 to 4 years in high-risk patients with ischemic or nonischemic cardiomyopathy. High-risk patients are identified primarily by heart failure class and a left ventricular ejection fraction of 30% to 35% or lower. Guidelines based on more limited evidence identify subgroups of high-risk patients with less common diseases, including hypertrophic cardiomyopathy (see Chapter 66) and ion channelopathies (see Chapters 32, 35, and 37).

Near-uniform consensus supports secondary-prevention guidelines, but support for primary-prevention guidelines is less consistent. On average, patients who receive ICDs in clinical practice are older and have more serious comorbid conditions, including diabetes and renal failure, than do patients in the foundational clinical trials. Retrospective analyses indicate that ICDs (excluding cardiac resynchronization devices) do not prolong life in identifiable subgroups of primary-prevention patients with extensive comorbidity. Additionally, approximately 15 to 20 primary-prevention ICDs must be implanted in asymptomatic patients to save one life. Not surprisingly, patients vary in their willingness to accept implantation of ICDs to treat statistical risk.

Single- Versus Dual-Chamber Pacemakers and Implantable Cardioverter-Defibrillators

Single- Versus Dual-Chamber Pacemakers

A recent expert consensus document provides guidelines for the selection of single- versus dual-chamber pacemakers and summarizes the supporting clinical evidence.⁷

Sinus Node Disease

In patients with sinus node disease, multiple randomized controlled trials have demonstrated that dual-chamber pacing is associated with a lower incidence of AF and pacemaker syndrome than single-chamber ventricular pacing is. These studies reported inconsistent results regarding reduction in heart failure, stroke, and quality of life. Dual-chamber pacemakers should be programmed to minimize right ventricular pacing in patients with intact AV conduction.

Rate-adaptive pacing is recommended for patients with significant symptomatic chronotropic incompetence who demonstrate improvement in symptoms after rate-adaptive pacing is programmed. Single-chamber atrial pacing is not generally recommended because many patients with sinus node disease are at risk for AV block, but it may be considered in patients with normal AV and ventricular conduction.

Atrioventricular Block and Bifascicular/Trifascicular Block

Dual-chamber pacing is recommended instead of single-chamber ventricular pacing in patients with these blocks based on expert consensus. However, randomized controlled trials performed exclusively or primarily in elderly, sedentary patients did not support the superiority of dual-chamber pacing for major endpoints other than pacemaker syndrome (e.g., AF, stroke, heart failure). Early, acute randomized studies demonstrated that dual-chamber pacing improves exercise tolerance when compared with fixed-rate ventricular pacing, but benefit over

rate-adaptive ventricular pacing has been inconsistent. Thus single-chamber ventricular pacing is an acceptable alternative to dual-chamber pacing in patients with AV block who have clinical conditions that limit the benefits of dual-chamber pacing (e.g. sedentary lifestyle) and in those in whom technical issues such as limitations in vascular access preclude or increase the risk associated with inserting an atrial lead.

Single- Versus Dual-Chamber Implantable Cardioverter-Defibrillators

Presently, expert consensus does not provide guidelines for the selection of single- versus dual-chamber ICDs. Dual-chamber ICDs provide dual-chamber pacing, diagnostics for AF, and discriminators of supra-ventricular tachycardia (SVT) and VT that are not available in single-chamber ICDs, and their stored EGMs provide higher diagnostic accuracy than single-chamber ones do. Disadvantages of dual-chamber ICDs include higher cost, atrial lead complications, and decreased longevity. Dual-chamber pacing modes that minimize ventricular pacing are important in ICD patients because of their high prevalence of left ventricular dysfunction, and they reduce the risk for heart failure as a result of obligatory right ventricular pacing in ICD patients. Randomized, controlled studies and a meta-analysis have shown a modest benefit of dual-chamber over single-chamber pacing for discrimination of SVT and VT in secondary-prevention patients in whom monomorphic VT occurs at rates that overlap the ventricular rates in SVT or sinus tachycardia. They show no benefit in primary-prevention patients and are unlikely to benefit secondary-prevention patients whose only arrhythmia is VF. Presently, there is no consensus regarding the use of single- versus dual-chamber ICDs, except in patients who require dual-chamber pacing.

HARDWARE

Pacing and Defibrillation Leads

Leads for pacing and defibrillation have in common a cable structure that connects the terminal pins, which are inserted into device receptacles called the “header,” as well as the electrodes used for sensing, pacing, or defibrillation (see Fig. 36-3). Pacing leads may have either bipolar or unipolar structures. With unipolar pacing leads, only one electrode is used for both sensing and pacing; the other electrode in the circuit is the pacemaker generator housing (can) itself. Unipolar pacing at high output may result in pectoral muscle stimulation because energy is dissipated from the pacemaker can. Unipolar sensing is much more likely to result in ventricular oversensing of noncardiac signals such as pectoral muscle myopotentials and electromagnetic interference because the can is part of the sensing circuit and the sensing dipole is large. Bipolar pacing leads have two electrodes between which sensing and pacing occur. Because the sensing dipole is smaller in bipolar sensing circuits than in unipolar circuits, oversensing of noncardiac signals is less common with bipolar sensing.

Oversensing of pectoral myopotentials with bipolar sensing often indicates a breach in lead insulation in the pacemaker pocket.

Defibrillation leads may have one or two sensing and pacing electrodes in addition to one or two defibrillation coils. If the defibrillation lead has two electrodes—a tip and a ring electrode—“true bipolar” sensing and pacing occur between these two electrodes. If the defibrillator lead has only a tip electrode, “integrated bipolar” sensing and pacing occur between the tip electrode and the distal defibrillator coil. The integrated bipolar design simplifies lead design by reducing the number of electrodes in the lead, but it incorporates a defibrillation electrode in the pacing circuit, which increases the likelihood of post-shock oversensing or undersensing.

All right ventricular defibrillation leads have a distal defibrillation coil (Fig. 36-3B). Dual-coil leads also have a proximal coil that is usually located in the superior vena cava or high right atrium. Some clinicians prefer single-coil leads because if extraction of the lead is required, proximal coil fibrosis presents the highest risk for serious injury to the superior vena cava. In right-sided implants, the use of dual-coil leads permits removing the can from the defibrillation circuit, which may improve the efficacy of defibrillation. Left pectoral implants are preferred over right pectoral implants for ICDs because the defibrillation vector to the can includes more of the left ventricle.

A subcutaneous ICD system has recently been approved (Fig. e36-2).⁸ This system consists of a single defibrillation coil implanted parallel to the sternum and tunneled to the ICD generator pocket located near the left anterior axillary line. It avoids the implant and intravascular infection risks associated with a transvenous lead, but the energy requirement for defibrillation is considerably higher than that needed for transvenous ICD systems, and it cannot deliver painless endocardial pacing. Thus it is not suitable if bradycardia pacing is indicated; patients' tolerance of subcutaneous ATP has not yet been evaluated. Follow-up for subcutaneous ICDs differs from that for transvenous ICDs because patients who have multiple episodes of shocked VT that might benefit from ATP or those who require dual-chamber or biventricular pacing may need revision to a transvenous system.

Pacemaker and Implantable Cardioverter-Defibrillator Generators

Pacemaker and ICD pulse generators (Fig. e36-3) have a clear plastic header, to which the leads are attached, and a titanium casing, or “can,” that houses the electronic components. The volume of the can is in the range of 10 to 15 cm³ for pacemakers and 30 to 35 cm³ for ICDs. Components common to both include the battery, voltage supply/control unit, microprocessor, ROM and RAM memory, telemetry control, system controller, rate-adaptive sensors, filters, sensing amplifier, and pacing output circuit/control unit. ICDs have additional high-voltage components, including a transformer, capacitor, and output circuitry.

Batteries. At implantation the battery's electrochemical potential represents the total lifetime energy available to the device for all

monitoring, processing, and therapeutic functions. Performance must be predictable over time to provide an elective replacement indicator.

Pacemakers use lithium iodine batteries. The pacing output circuit/control unit acts to convert the battery voltage to the desired voltage output for pacing. Unlike pacemaker batteries, ICD batteries must be able to deliver high current (up to 3 A) and high power (up to 10 W) for several seconds to charge the high-voltage capacitors (Table e36-1). ICDs often use lithium silver vanadium oxide or lithium manganese dioxide batteries. Batteries have an energy density exceeding 3000 J/cm³.

Implantable Cardioverter-Defibrillator High-Voltage Charging Circuits. The high-voltage charging circuit converts the low-voltage output of the battery into the high voltage that charges the shock output capacitor. A special direct current (DC)-to-DC converter/step-up transformer converts the 3.2 V up to the 800 V needed for defibrillation. The charge is stored on a capacitor and then delivered as a single shock. The efficiency of charging circuits is in the range of 50%, and it typically takes 6 to 15 seconds to charge the high-voltage capacitor to maximum voltage (usually 800 to 900 V) and store about 40 J of energy in the capacitor. All ICDs use a biphasic waveform in which the polarity of the waveform is reversed in the middle of the shock.

The High-Voltage Capacitor. A capacitor consists of two conductors separated by an insulator (dielectric). They store electrical charge on the surface of the conductors, store electrical energy in the field between the two conductors, and determine the duration required to deliver the shock defibrillation waveform. The energy stored in a capacitor is derived by

$$E_{\text{std}} = \frac{1}{2} CV^2$$

This equation links stored energy—a key determinant of ICD size—to the voltage stored on the capacitor, which except for minimal voltage loss in the output circuit, is equal to the initial shock waveform voltage (V). ICD capacitors have an energy density that ranges from 3 J/cm³ for aluminum electrolytic capacitors to 5 J/cm³ for tantalum powder capacitors, almost 1000 times less than that for batteries.

SENSING VERSUS DETECTION

Sensing. Delivery of appropriate electrical therapy depends on sensing of cardiac depolarizations and detection of arrhythmias by analysis of the timing and morphology of sensed events. When a depolarization wave front passes the tip electrode of an intracardiac lead, a deflection in the continuous EGM signal travels instantaneously via the electrode to the pulse generator. There, the signal is amplified, filtered, digitized, and processed by the sensing electronics (Fig. 36-5). A sensed event is an instant in time when the device determines

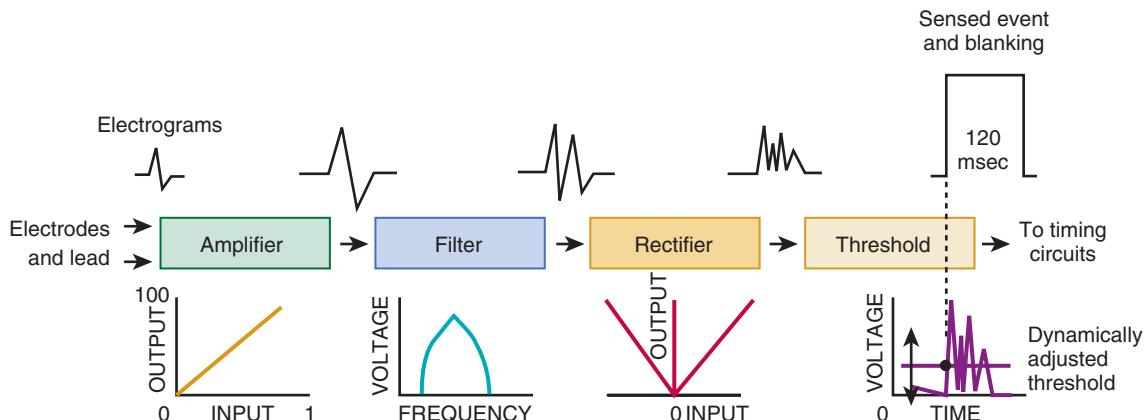

FIGURE 36-5 Functional block diagram for a pacemaker or ICD sense amplifier. The EGM signal from the two implanted electrodes is first amplified for subsequent processing. Band pass filtering reduces the amplitude of lower-frequency signals, such as T waves and far-field R waves, and higher-frequency signals, such as myopotentials and electromagnetic interference. After band pass filtering, the signal is rectified to remove polarity information. The amplified, filtered, and rectified signal is then compared with the sensing threshold voltage, which is adjusted automatically over time in an inverse relationship to the amplitude of sensed events. At the instant that the processed signal exceeds the sensing threshold, a sensed event is declared to the ICD. Simultaneously, the sense amplifier is blanked (turned off) for a short time, depending on the pacemaker or ICD model (120 milliseconds in this example), so that each depolarization is sensed only once. In actual circuits, some functions, such as amplification and filtering, may be integrated.

FIGURE e36-2 Diagram of a transvenous ICD system (**left panel**) and subcutaneous ICD system (**right panel**). A single-chamber transvenous ICD system includes a left pectoral active can and right ventricular (RV) lead. The dual-coil lead uses true bipolar sensing between the tip and ring electrodes. Sensing occurs between the tip and ring electrodes of a true bipolar lead or the tip and RV coil electrodes of an integrated bipolar lead. Defibrillation occurs between the distal RV coil and the ICD can. In dual-coil leads, the proximal coil is linked to the can for defibrillation. In a subcutaneous ICD system, the pulse generator is positioned in or near the left midaxillary line. Defibrillation occurs between the housing (can) of the generator and an 8-cm-long, left parasternal coil electrode. Sensing is performed with one of three pairs of electrodes, chosen among the can and small sensing electrodes proximal and distal to the coil. (**Left panel**, From Swerdlow CD, Friedman P: *Implantable cardioverter-defibrillator*. In Zipes D, Jalife J [eds]: *Clinical Aspects in Cardiac Electrophysiology: From Cell to Bedside*. 6th ed. Philadelphia, WB Saunders [in press]; **right panel**, from Boston Scientific.)

TABLE e36-1 Power Considerations Influencing Battery Selection for Pacemakers and Implantable Cardioverter-Defibrillators

ACTIVITY	FREQUENCY	POWER DEMAND RANGE (μW)	
		Low	High
Sensing	Constant	20	30
Pacing	Frequent or Infrequent	20	100
Telemetry	Infrequent	1000	5000
Defibrillation	Rare	2,000,000	10,000,000

that an atrial or ventricular depolarization has occurred on the basis of processing the continuous EGM signal.

Both pacemakers and ICDs use the measured intervals between sensed events to control pacing on a beat-by-beat basis. There are four relevant intervals: those between atrial events (A-A), between ventricular events (V-V), between an atrial event and the next ventricular event (AV), and between a ventricular event and the next atrial event (VA). However, sensing in pacemakers and sensing in ICDs have major differences: ICDs need reliable sensing of low-amplitude EGMs during VF, whereas pacemakers do not. ICDs cannot use unipolar EGMs for sensing. In contrast, pacemakers may sense either unipolar or bipolar EGMs.

Detection. Software in pacemakers and ICDs processes sensed events to classify the atrial or ventricular rhythm and thus detect the presence of tachyarrhythmias. This software, referred to as a detection algorithm, is used to change the pacing mode in response to atrial tachycardia or AF, to store data about untreated tachyarrhythmias, and to treat tachyarrhythmias with ATP or shocks.

Sensing Thresholds. In older pacemakers and many modern pacemakers, sensing thresholds are programmed to fixed values. Ventricular channels typically operate at thresholds of 2.0 to 3.5 mV, approximately 10 times less sensitive than those in ICDs. Atrial sensing thresholds typically operate at 0.3 to 0.6 mV to allow sensing of lower-amplitude P waves and atrial EGMs during AF. Highly sensitive programmed values can result in sensing of unintended signals not originating in the cardiac chamber of interest, referred to as oversensing. EGMs sensed from a different cardiac chamber (usually ventricular signals sensed on the atrial channel) are referred to as far-field EGMs. Oversensing of far-field cardiac and extracardiac signals may result in inappropriate pacemaker inhibition or tracking, especially with unipolar sensing. See Troubleshooting, later.

In ICDs the guiding principle is that sensing of VF should be sufficiently reliable that clinically significant delays in detection do not occur. Although high sensitivity is required to ensure reliable sensing of VF despite variable- and low-amplitude EGMs, continuous high sensitivity can result in oversensing of cardiac or extracardiac signals during regular rhythm. To minimize both undersensing during VF and oversensing during regular rhythms, ICDs use feedback mechanisms based on R wave amplitude to adjust the sensing threshold dynamically, starting with a high threshold and gradually decreasing the threshold to permit sensing of small R waves (automatic adjustment of sensitivity; **Fig. 36-6**).

FIGURE 36-6 Dynamic versus fixed sensing threshold in VF. **A**, Fixed sensitivity requires that the sensed potential exceed a fixed threshold. Because of the highly variable amplitude during VF, undersensing occurs (arrows). If the threshold is lowered, T wave oversensing may take place (note that the threshold is just above the T wave amplitude during sinus rhythm, first two complexes). **B**, Dynamic adjustment of sensitivity. The gain is fixed, but the threshold for sensing changes throughout the cardiac cycle. Undersensing is diminished. (Modified from Olson WH: Tachyarrhythmia sensing and detection. In Singer I [ed]: Implantable Cardioverter-Defibrillator. Armonk, NY, Futura, 1994, pp 71-107.)

PACING MODES, TIMING CYCLES, BLANKING, AND REFRACTORY PERIODS

Pacing Modes

The most commonly used nomenclature for pacing modes involves a four-letter code (**Table 36-1**). The first letter stands for the chamber paced: A for atrium, V for ventricle, and D for dual—both atrium and ventricle. The second letter stands for the chamber sensed: A for atrium, V for ventricle, and D for dual—both atrium and ventricle. The third letter is the function: I for inhibition, T for triggered, and D for dual tracking of atrial activity while inhibited by ventricular activity. The fourth letter is R for rate adaptive. The letter “O” indicates absence of that function.

Often it is easier to analyze pacing modes in terms of their associated time intervals (or “periods”) measured in milliseconds than in terms of their rate measured in beats/min. One advantage of using intervals is that they can be added. A second advantage is that intervals accurately describe a cardiac rhythm that varies from beat to beat whereas rate refers to an average value if the rhythm is irregular. Because 1 minute is equivalent to 60,000 milliseconds, the interval in milliseconds corresponding to a rate in beats/min can be determined by dividing the rate into 60,000 (**Table e36-2**).

The VVI mode is the basic single-chamber ventricular pacing mode; it allows pacing to occur when the ventricular rate slows below the programmed lower rate limit (**Fig. 36-7**). The interval corresponding to the lower rate limit is the ventricular pacing interval. Usually, this is equal to the interval between a sensed ventricular event and the next paced ventricular event, referred to as the “ventricular escape interval.” There is no atrial sensing, so AV synchrony is not preserved. This mode is indicated for patients with permanent AF.

The AAI mode is the corresponding single-chamber atrial pacing mode (**Fig. 36-8**). It is appropriate for patients with sinus node dysfunction and normal AV conduction. Because it does not provide ventricular pacing, it should not be used in patients at risk for AV block.

The DDD pacing mode is most commonly used in the patients whose rhythm is not permanent AF (**Fig. 36-9**). In this mode the atrial rate cannot go lower than the programmed lower rate. A programmed AV delay is the maximum time permitted from an atrial event to a ventricular event. If a spontaneous ventricular event does not occur by the time that the AV delay elapses, a ventricular paced event occurs. In the setting of AV block, all ventricular events are paced. A special characteristic of the DDD pacing mode is the ability to “track” intrinsic atrial activity to maintain AV synchrony.

The DDD mode has an upper rate limit, the maximum rate that intrinsic atrial activity will be tracked. The maximum rate is selected to exceed the maximum sinus rate that the patient is capable of achieving. The upper rate limit is predominantly of importance to prevent tracking of rapid atrial activity in spontaneous atrial arrhythmias such as AF.

Blanking and Refractory Periods Definitions

At slow ventricular rates, most of the cardiac cycle constitutes a sensing alert period during which sensed events are used for both pacemaker timing cycles and detection of tachyarrhythmias. After each sensed event the sense amplifier is turned off for a short blanking period (20 to 250 milliseconds) to prevent multiple sensed events during a single cardiac depolarization. Following each blanking period there is a refractory period during which events may be sensed for tachyarrhythmia detection algorithms but do usually not alter pacemaker timing cycles (**Fig. 36-10**; also see **Figs. 36-5 and 36-7 to 36-9**).

TABLE e36-2 Interval Versus Rate

Bradycardia

FIGURE 36-7 The VVI timing cycle consists of a defined lower rate limit and a ventricular refractory period (VRP, represented by rectangles). When the ventricular escape interval (VEI) from the ventricular sensed event of 1000 milliseconds is completed, a paced event occurs. Because no ventricular sensed event occurs within 1000 milliseconds after the paced event, a second ventricular paced event occurs. Because a ventricular sensed event occurs 800 milliseconds later, a ventricular paced event does not occur. A VRP begins with any sensed or paced ventricular activity.

FIGURE 36-8 The AAI timing cycle consists of a defined lower rate limit and an atrial refractory period (ARP, represented by rectangles). When the atrial escape interval (AEI) from the atrial sensed event of 1000 milliseconds is completed, a paced event occurs. Because no atrial sensed event occurs within 1000 milliseconds after the paced event, a second atrial paced event occurs. Because an atrial sensed event occurs 800 ms later, an atrial paced event does not occur. An ARP begins with any sensed or paced atrial activity.

The blanking and refractory periods in the ventricle after atrial sensed or paced events and in the atrium after ventricular sensed or paced events are called cross-chamber blanking and refractory periods. Cross-chamber blanking periods reduce oversensing of the pacing artifact after a paced event in the opposite chamber. The postventricular atrial blanking period (after ventricular events) reduces atrial oversensing of ventricular pacing stimuli and far-field R waves, which may result in incorrect diagnosis of an atrial tachyarrhythmia. ICDs typically have shorter blanking and refractory periods than pacemakers do so that short cardiac cycles can be sensed reliably.

Postventricular Atrial Refractory Period

In the DDD mode, there is a special refractory period called the post-ventricular atrial refractory period (PVARP) that starts with any

FIGURE 36-9 The timing cycle in DDD consists of a lower rate limit, an AV interval, a ventricular refractory period, a PVARP, and an upper rate limit. Because an intrinsic atrial event occurs and is followed by an intrinsic ventricular event within the AV interval, no ventricular pacing occurs in the first beat. In ventricular-based timing, the time from a ventricular paced or sensed event to the next atrial paced event is called the atrial escape interval (AEI), which is the lower rate limit interval minus the AV interval. Because no intrinsic atrial event occurs, a paced atrial event occurs. Because no intrinsic ventricular event occurs after this atrial paced event within the AV interval, a ventricular paced event occurs. Following this ventricular paced event an atrial paced event of 800 milliseconds occurs within the AEI. However, AV conduction follows this atrial paced event. The final event is an atrial intrinsic event that is not followed by an intrinsic ventricular event within the AV interval. Hence the intrinsic atrial event is “tracked” and followed by a paced ventricular event. If intrinsic atrial and ventricular activity occurs before the lower rate limit times out, both channels are inhibited and no pacing occurs. In the absence of intrinsic atrial and ventricular activity, AV sequential pacing occurs (first cycle). If no atrial activity is sensed before the VA interval is completed, an atrial pacing artifact is delivered, which initiates the AV interval. If intrinsic ventricular activity occurs before termination of the AV interval, ventricular output from the pacemaker is inhibited, that is, atrial pacing (second cycle). If a P wave is sensed before the VA interval is completed, output from the atrial channel is inhibited. The AV interval is initiated, and if no ventricular activity is sensed before the AV interval terminates, a ventricular pacing artifact is delivered, that is, P-synchronous pacing (third cycle).

ventricular event and defines a period on the atrial channel during which a spontaneous atrial event is not tracked. The PVARP is especially important in patients with retrograde conduction. If the PVARP is too short, a premature ventricular beat may be conducted retrogradely, sensed on the atrial channel, and tracked, thereby resulting in a second (paced) ventricular beat that can be conducted retrogradely. This repetitive sequence of ventricular pacing, retrograde conduction, and atrial tracking of the retrogradely conducted beat represents one form of pacemaker-mediated tachycardia (Fig. e36-4).

The PVARP has important implications regarding upper rate behavior. Because the ventricular rate cannot exceed the programmed upper rate limit, an algorithm is needed to determine how the ventricular pacing rate should be adjusted in patients with AV block when the sinus rate exceeds the upper rate limit. All pacemakers share the algorithm for extending the AV delay when the sinus rate

FIGURE e36-4 Example of pacemaker-mediated tachycardia (PMT). The **top channel** shows a far-field EGM similar to a surface ECG. The second channel gives the ventricular EGM. Below are the atrial and ventricular markers. Each ventricular paced event is followed by an intrinsic atrial event. In the **bottom panel** this pattern is identified as PMT. The final atrial sensed event following the last ventricular paced beat is not tracked and is followed by an atrial paced beat that is conducted to the ventricle. This stops the PMT.

FIGURE 36-10 Schematic representation of the timing cycle interactions of most refractory and blanking periods in contemporary dual-chamber pacemakers. **Top**, Atrial channel; **bottom**, ventricular channel. PVAB = postventricular atrial blanking.

exceeds the upper rate limit so that the ventricular pacing rate is at the programmed upper rate. Because the sinus rate is faster than the ventricular pacing rate, P waves will occur progressively earlier after each successive ventricular paced beat. Eventually the sinus beat falls within the PVARP and is no longer tracked. This progressive prolongation of the AV delay until a sinus beat times in the PVARP and is not followed by a paced ventricular beat is often called “pseudo-AV Wenckebach.” Unlike biologic Wenckebach, the ventricular rate remains constant at the upper rate limit.

If the sinus rate increases further so that every other P wave will time within the PVARP, the pacemaker will track every other P wave and thereby result in 2:1 atrial tracking. Consider the slowest atrial rate that results in 2:1 atrial tracking. The tracked P wave will be followed by a ventricular paced beat at the programmed AV interval, and the ventricular beat will be followed by the nontracked P wave exactly by the duration of the PVARP. Thus the time from the tracked P wave to the nontracked P wave equals the sum of the programmed AV delay and the PVARP, which is called the total atrial refractory period (TARP). Such 2:1 tracking results in an abrupt decrease in the ventricular rate (Fig. 36-11) and often causes exertional intolerance if it occurs during exercise-induced sinus tachycardia. Consequently, it is important to keep the TARP below the maximum sinus rate during exercise.

The DDI pacing mode is similar to the DDD mode but lacks atrial tracking and therefore an upper rate limit. It can be used in patients with sinus bradycardia, with or without intact AV conduction. Today it is rarely programmed unless atrial sensing problems prevent reliable DDD pacing. The VDD pacing mode is suitable for patients with intact sinus node function and AV block because only the ventricular chamber is paced but sensing occurs in both the atrium and ventricle. Intrinsic sinus beats are tracked as in the DDD mode. A special lead with floating atrial electrodes for sensing and standard ventricular electrodes for pacing and sensing permits single-lead VDD pacing.

Rate-Adaptive Pacing

Rate-adaptive pacing adjusts the pacing rate to the metabolic demands of the body. A sensor located in the pacemaker generator or lead monitors a signal that may indicate the need for an increased heart rate. Commonly used sensors monitor body motion (accelerometer), respiration (minute ventilation), or cardiac motion (endocardial acceleration), and each has specific advantages and limitations. Algorithms translate the sensor values to a pacing rate. Most algorithms have programmable parameters to achieve the optimal heart rate for the body's metabolic needs.

FIGURE 36-11 When the sinus rate exceeds the programmed maximum tracking rate and the P-to-P interval is shorter than the sum of the atrioventricular interval (AVI) and the PVARP, every other P falls within the PVARP and therefore cannot be tracked. Thus the ventricular rate is half the atrial rate.

Automatic Mode Switching

Automatic mode switching in the DDD pacing mode initiates a temporary change in mode to a nontracking one (usually DDI or DDIR) during paroxysmal atrial tachyarrhythmias. This prevents the adverse consequences of rapid ventricular pacing as a result of tracking nonphysiologic high atrial rates. Most mode-switching algorithms use the atrial rate as an indicator for the onset of an atrial tachyarrhythmia. When the atrial rhythm again meets the defined criteria for a physiologic rhythm, the mode switches back to an atrial tracking mode (Fig. 36-12).

Pacing Algorithms to Avoid Unnecessary Right Ventricular Pacing

Because only a small proportion of patients with sinus node dysfunction receive a single-chamber AAIR pacemaker, strategies to minimize right ventricular pacing are important to reduce the adverse clinical effects of unnecessary right ventricular pacing and to prolong generator longevity. One common strategy in patients with AV conduction is a variation on AAIR pacing with back-up ventricular pacing. Such algorithms perform in the AAIR pacing mode when AV block is not present but switch automatically to the DDDR mode when AV block is detected. This algorithm also checks periodically to determine whether AV conduction has resumed and returns to AAIR pacing when conduction resumes. The advantage of this commonly used approach is that it can be tolerant of occasional single beats of AV block without resorting to consistent ventricular pacing but provides ventricular pacing with a physiologic AV interval. These algorithms are programmed commonly, but they may mimic intermittent failure of ventricular pacing for a single beat. They may be differentiated from oversensing in that ventricular tracking always resumes after a blocked P wave (Fig. 36-13).

FIGURE 36-12 Mode switch from the DDDR to the DDIR mode.

FIGURE 36-13 Example of an algorithm to minimize right ventricular pacing. Initially, AAI pacing is seen; if an atrial pace event occurs without a ventricular sensed event, a ventricular backup output occurs and the pacemaker then switches to the DDDR mode.

An alternative strategy is to prolong the AV interval to allow intrinsic AV conduction. If intrinsic ventricular activation is detected, the AV delay remains extended. If ventricular activation is not detected within a given AV delay range, ventricular pacing resumes. This prevents single beats of AV block, but it usually results in a higher percentage of ventricular paced beats. Periodic extension of the AV delay to detect intrinsic ventricular activation is termed “positive search AV hysteresis.” Either strategy may result in the extremely long AV delays that cause pacemaker syndrome.

Automatic Optimization of Other Pacemaker Function Based on Sensing

Pacemakers and ICDs also incorporate algorithms to optimize function based on sensing. These include algorithms to prevent inhibition during oversensing and loss of pacemaker capture. Ventricular safety pacing prevents inappropriate pacemaker inhibition caused by ventricular oversensing of atrial pacing stimuli (crosstalk; **Fig. e36-5**). Safety pacing may be identified on ECGs by noting a shorter than programmed AV delay, usually 80 to 130 milliseconds. Noise reversion to fixed-rate asynchronous pacing prevents pacemaker inhibition during continuous ventricular oversensing, including that occurring during electromagnetic interference from sources such as electrocautery. Automatic assessment of the pacing capture threshold is performed by closed-loop feedback algorithms that periodically test capture and adjust the output based on test results. This

feature permits use of an output that is just sufficient to achieve capture and results in safety, as well as conservation of battery energy.

DETECTION OF VENTRICULAR TACHYCARDIA AND FIBRILLATION IN IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

Rate, Duration, and Detection Zones

The primary criteria used for detection of VT and VF are the ventricular rate and duration. Ventricular intervals can be measured and counted with minimal power consumption, whereas more complex algorithms require additional processing power. The ICD determines whether the ventricular rhythm is fast enough for a sufficiently long period to warrant further analysis.

ICDs have up to three ventricular rate detection zones that permit programming of zone-specific therapies and SVT-VT discriminators, although two zones are sufficient in many patients—one VT zone and one “VF” zone (**Fig. 36-14**). In secondary-prevention patients (those with a history of spontaneous VT or VF), the VT detection rate should be programmed at least 20 beats/min slower than any documented sustained VT. Three-zone programming is indicated in many such patients to permit different ATP for two distinct rates of VT. Typical values for these rate boundaries are 350 to 500 milliseconds for slower VT, 300 to 350 milliseconds for faster VT, and 240 to 300 milliseconds for VF. In primary-prevention patients, programming a high rate cutoff of 180 to 200 beats/min is safe and reduces “inappropriate therapy” delivered during a rhythm other than VT/VF.⁹ In

the VF zone, ATP is programmed during or before charging, followed by shocks. Many ICDs permit programming of an additional monitor-only zone between the sinus and VT zones.

Duration is the time or number of intervals required to satisfy the rate criterion. Longer durations permit “unnecessary therapy” for VT/VF that would have terminated spontaneously if therapy had been delayed. Prospective randomized trials of primary-prevention patients report fewer shocks when using a duration of 30 beats/min (up to 10 seconds) for VT faster than 180 beats/min¹⁰ or 60 seconds for VT between 170 and 199 beats/min, without an increase in mortality.⁹ Also in primary-prevention patients, programming a single detection zone at 200 beats/min or greater with a 2.5-second delay results in approximately equivalent shock reduction without a statistically significant increase in overall syncope.⁹

Supraventricular-Ventricular Tachycardia Discriminators

Because SVT and VT can overlap in rate, particularly in patients with slower VT, ICDs have specific algorithms to discriminate SVT from VT. These include single-chamber ventricular discriminators and dual-chamber discriminators. Single-chamber discriminators include sudden onset, ventricular rate stability (regularity), and morphology of the ventricular EGM. The sudden-onset criterion uses a difference in cycle length that is greater than a programmed percentage (e.g.,

FIGURE e36-5 Crosstalk inhibition. **Upper panel**, Surface ECG showing intermittent failure of ventricular output when the surface ECG is assessed. **Lower panel**, Dual-chamber marker channel and real-time ventricular EGM showing oversensing during the AV interval of a high-amplitude potential that saturates the sensing amplifier. See text for details. FVT = fast ventricular tachycardia. Some ICDs permit programming of an additional monitor-only zone. (From Swerdlow CD, Friedman P: *Implantable cardioverter-defibrillator*. In Zipes D, Jalife J [eds]: *Clinical Aspects in Cardiac Electrophysiology: From Cell to Bedside*. 6th ed. Philadelphia, WB Saunders [in press].)

9% to 50%) or a difference in value (50 to 250 milliseconds) to meet detection. It is useful for preventing detection of gradually accelerating sinus tachycardia, but it may cause underdetection of a VT that begins slower than the VT rate criterion or occurs during sinus tachycardia that is faster than the VT rate threshold. Rate stability is used to discriminate irregular conduction during AF from regular ventricular rates during monomorphic VT. Morphology algorithms discriminate VT from SVT based on changes in the shape of the ventricular EGM that occur when the source of the EGM is not related to conduction of supraventricular impulses through the His-Purkinje system. These are analogous to changes in the morphology of the QRS complex used to discriminate VT from SVT on the surface ECG.

Dual-chamber algorithms incorporate comparison of atrial and ventricular rates, the absolute atrial rate during AF, and the AV relationship to enhance diagnostic accuracy. If the ventricular rate exceeds the atrial rate, the diagnosis is always VT, provided that atrial sensing is reliable. However, if the atrial rate is equal to the ventricular rate, additional single- or dual-chamber criteria must be used to discriminate the 1:1 AV conduction of SVT from the 1:1 VA conduction of VT. If the atrial rate exceeds the ventricular rate, additional criteria must be used to discriminate rapidly conducted atrial arrhythmia from VT or VF occurring during an atrial tachyarrhythmia (Fig. 36-15).

ELECTRICAL THERAPY FOR VENTRICULAR TACHYARRHYTHMIAS

Once VT or VF is detected, the ICD delivers a progression of up to six therapies consisting of trains of ATP or individual high-voltage shock therapies (see Chapter 35). After each delivered therapy, the ICD's "redetection algorithm" monitors the rhythm for termination of VT/VF and resumption of sinus rhythm, persistence of the same VT/VF, or change in VT/VF. Therapies escalate in "tiers" from low-power ATP to high-power shocks. Therapy sequences are programmable independently for up to three detection zones based on the ventricular rate: slow VT, fast VT, and VF.

Antitachycardia Pacing

ATP (Fig. 36-16) consists of 3- to 10-beat trains of pulses at a cycle length shorter than the VT cycle length. In contrast to bradycardia pacing, which is usually delivered with a fixed cycle length, ATP is applied in an adaptive mode with the first pulse set to a percentage of the preceding VT cycle length, typically 85% to 90% for faster VTs and 75% to 85% for slower VTs. ATP may be delivered in either a "burst" or "ramp" mode. In the burst mode, pulses within a train have a fixed cycle length, which may be decreased by 10 to 30 milliseconds between successive trains if the first train does not terminate the VT. In the ramp mode, sequential pulses within each train are delivered at progressively shorter cycle lengths until a minimum value is reached.

For ATP to be successful, at least one pulse must enter the reentry circuit, terminate the VT, and not reinitiate VT (see Chapter 33). ATP is the primary therapy delivered by ICDs to treat monomorphic VT, which accounts for approximately 90% of all VT/VF treated by an ICD, but it is rarely effective for polymorphic VT or VF. It terminates approximately 50% of faster VTs (above ≈ 180 beats/min) and 80% of slower VTs that would otherwise require a shock.¹¹ Painless termination of VT improves quality of life in ICD patients much more than painful shocks do.⁹ Usually, one or two sequences of ATP are programmed for faster VTs and two to four sequences for slower VTs. Two sequences terminate approximately 90% of VTs that can be terminated by ATP.

Cardioversion and Defibrillation Shocks

Although monomorphic VTs can often be terminated by low-energy cardioversion (synchronized shocks ≤ 5 J), weak shocks risk acceleration of VT to VF because the vulnerable period during VT may extend to the subsequent R wave. We usually recommend programming high-energy (≥ 20 J) shocks for VT because delays in charging the capacitor are less significant clinically during VT than during VF and shock pain is not dependent on shock strength.

The first defibrillation shock is programmed either to a patient-specific value (determined in relation to the weakest shock strength

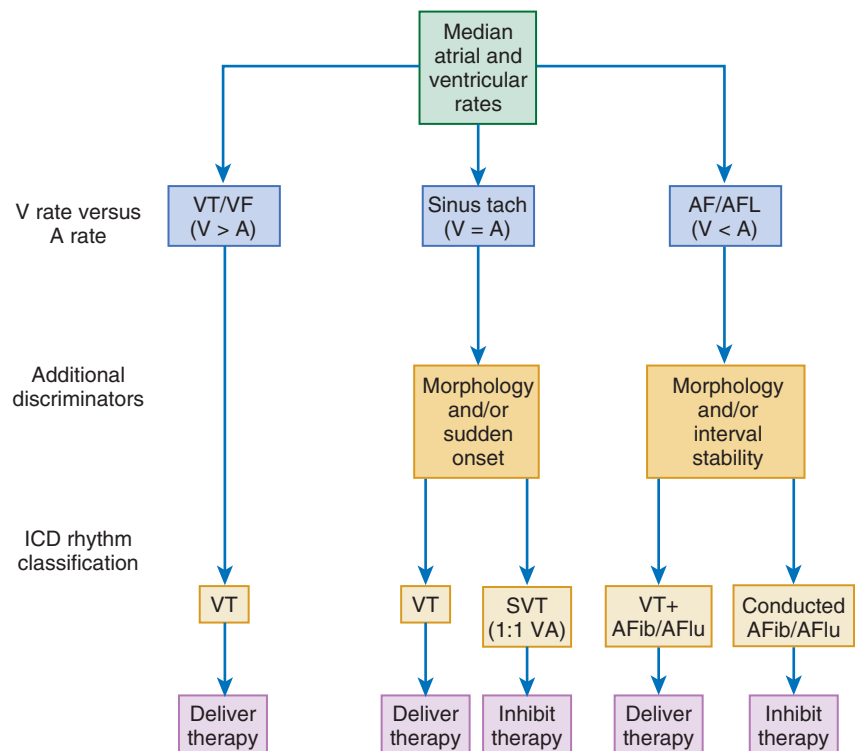

FIGURE 36-15 Features of a dual-chamber SVT-VT discrimination algorithm. This figure is based on the algorithm used in St. Jude Medical ICDs, but all three U.S. ICD manufacturers use conceptually similar algorithms. "Morphology" refers to the morphology of the ventricular EGM. AFib/AFlu = atrial fibrillation/atrial flutter.

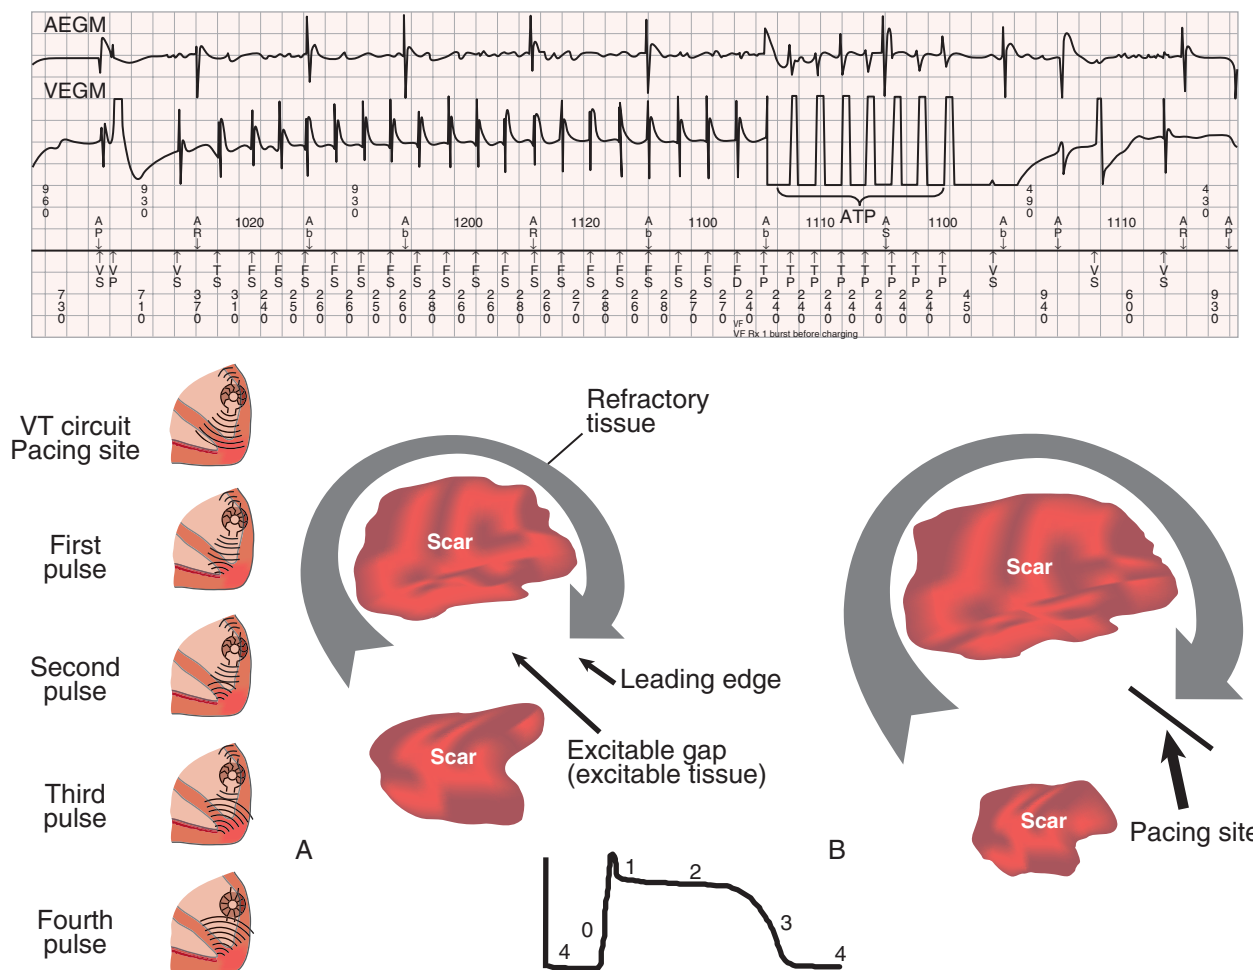

FIGURE 36-16 ATP for monomorphic VT: stored atrial (AEGM) and ventricular (VEGM) electrograms and atrial and ventricular marker channels from an episode of rapid monomorphic VT (cycle length, 240 to 270 milliseconds; rate, 220 to 250 beats/min). VT with AV dissociation begins with the second VEGM. After 18 intervals shorter than the programmed VF detection interval of 320 milliseconds, an adaptive train of eight ATP pulses is delivered at a cycle length of 240 milliseconds, 88% of the VT cycle length, to terminate the VT. On the marker channel, VS, TS, and FS indicate intervals classified in the sinus, VT, and VF rate zones, respectively. FD = detection of VF; TP = ATP. Note that a burst of ATP is delivered even though the intervals are in the VF zone. AP = atrial paced events. Ab and AR indicate atrial intervals in the postventricular atrial blanking and refractory periods, respectively. At the **left**, vertical panels show a conceptual model of why multiple ATP pulses are required in a train. The **top panel** shows that during VT the region between the pacing lead in the right ventricular apex and the VT reentry circuit in the left ventricle is activated by the circuit. Subsequent panels represent conditions after the first, second, third, and fourth ATP pulses. After each successive pulse, ATP propagates to more of the region before colliding with the VT wavefront. The **lower panel** shows a conceptual model of the interaction between ATP pulses and the VT circuit. In **A**, the circuit around a fixed scar is depicted by the arrow. The head of the arrow depicts the leading edge of the wavefront, and the body of the arrow back to the tail (colored gray) represents depolarized tissue that is refractory because the wavefront has just propagated through it. The repolarized tissue between the tip and the tail of the arrow is excitable ("excitable gap"). For the head of the arrow to continue around the scar, an excitable gap must be present; if the wavefront encounters refractory tissue, it cannot proceed. In **B**, a wavefront generated by an ATP pulse enters the excitable gap and terminates the VT. Tachycardias with a small excitable gap (i.e., the head of the arrow follows the tail very closely so that only a small "moving rim" of excitable tissue is in the circuit) are less likely to be terminated with ATP. (**Lower panel**, From Hayes DL, Friedman PA [eds]: *Cardiac Pacing and Defibrillation: A Clinical Approach*. 2nd ed. West Sussex, United Kingdom, Wiley-Blackwell, 2008.)

that achieved defibrillation during implant testing) or to a maximum output of 30 to 40 J. In adults, subsequent shocks are generally programmed to maximum output. A patient-specific strategy minimizes the potential long-term adverse effects of excessive programmed shock strength, such as myocardial depression, but clinical benefit has not been established. It also reduces charge times if they are prolonged toward the end of service and thus reduces delay to delivery of a shock.

Maximum-output shocks terminate induced VF at ICD implantation in approximately 90% of patients when the initial system configuration is used and in more than 95% of patients after system revision in selected patients, but first ICD shocks at the same shock strengths terminate only 80% to 90% of rhythms detected as VF during clinical follow-up despite the fact that most of these rhythms are VT. Thus the success of shocks for clinical VT/VF may depend on factors that are not evaluated at implantation (e.g., ischemia, autonomic tone, drugs, activity, or disease progression). In some cases, VT does not appear to terminate despite multiple shocks and low DFTs, possibly because

the shocks reinduce VT. However, approximately 98% of all spontaneous VT/VF is terminated by the first two shocks.

Shock Reduction

ICD shocks provide the only effective therapy for many life-threatening episodes of VT and VF. The initial observational and subsequent randomized controlled trials in which it was demonstrated that ICDs improve survival were performed with devices in which shocks consisted of the primary therapy for VT/VF. In the last decade, health care providers have focused on the important adverse psychosocial consequences of shocks (see Chapter 86). Recent data confirm that shocks increase the use of medical care. There is a strong correlation between ICD shocks and patient mortality.¹² Experts agree that this correlation is primarily due to more advanced heart disease in patients who receive shocks than in those who do not, but they disagree on whether shocks play an incremental, independent causal role.

TABLE 36-2 Implantable Cardioverter-Defibrillator Programming for Primary and Secondary Prevention of Patients

		PRIMARY PREVENTION		
		Strategy 1	Strategy 2	Strategy 3
Zone 1: VT				
Programmed rate (beats/min)*	≥20 slower than the slowest VT [†]	170-199	170-199	167-181
Duration for detection (sec)	≥9		60	10-12
SVT-VT discrimination	Yes		Yes	
Therapy	ATP × 2-4 Maximum shocks	Monitor only	ATP × 2-4 Maximum shocks	Monitor only
Zone 2: Faster VT				
Programmed rate (beats/min)*	188-249	≥200	200-249	182-249
Duration for detection (sec)	9	2.5	12	9
SVT-VT discrimination	Yes	No	Yes	Yes
Therapy	ATP × 1-2 [‡] Maximum shocks	ATP × 1 [‡] Maximum shocks	ATP × 2-4 Maximum shocks	ATP × 1-2 [‡] Maximum shocks
Zone 3: Fastest VT/VF				
Programmed rate (beats/min)*	≥250	NA	≥250	≥250
Duration for detection (sec)	9		2.5	9
SVT-VT discrimination	No		No	No
Therapy	ATP × 1 [‡] Maximum shocks		ATP × 1 [‡] Maximum shocks	ATP × 1 [‡] Maximum shocks

*ICD counting methods require approximately 75% of beats to be faster than this rate.

[†]If the slowest VT is less than 200 beats/min.

[‡]Reduced delay between ATP and the first shock.

NA = not applicable.

TABLE 36-3 Programming Principles for Shock Reduction*

PRINCIPLE	RATIONALE
Long detection time	Do not treat self-terminating VT
Fast VT detection rate in primary-prevention patients	Do not treat slower tachycardias, which are more likely to be SVT
SVT-VT discrimination	Do not treat SVT
ATP in all VT/VF detection zones	ATP is painless. Even in the "VF" zone, most rhythms are monomorphic VT, and many can be terminated by ATP
Maximum shock strength	Minimize unsuccessful shocks for VT, VF, or AF with a rapid ventricular rate

*Provided that AV conduction is normal and the discriminator is reliable.

Recent recommendations have emphasized the importance of both non-device-related interventions and programming to minimize ICD shocks.^{9,11} These are summarized in **Tables e36-3, 36-2, and 36-3**. Non-device-related interventions include basic treatment of metabolic abnormalities, ischemia, and heart failure, as well as the use of beta blockers, antiarrhythmic drugs, and catheter ablation. Programming principles include not treating self-terminating VT, SVT, or slow VT (in primary-prevention patients); minimizing shocks delivered because of sensing problems; use of ATP as the initial therapy for VT; and programming high-energy shocks to reduce the number of arrhythmias that require multiple shocks.

TROUBLESHOOTING COMMON CLINICAL PROBLEMS

Noninvasive troubleshooting tools include the history, chest radiograph, surface ECG, stored device data (programming, lead impedance values and trends, stored EGMs, and marker channels), and real-time device data (pacing and sensing thresholds, real-time EGMs

during pocket manipulation or arm motion). For ICDs they include induction of VF to test sensing of VF and defibrillation.

Pacemakers

The most common pacing problems can be classified as failure to capture, failure to pace, pacing at a rate inconsistent with the programmed rate, and unanticipated rapid pacing (**Table 36-4**).

Failure to Capture

Failure to capture is defined as a pacing stimulus without subsequent cardiac depolarization (**Fig. 36-17**). It may be related to the pacing system, the patient, or patient-system interactions. The most common cause is an elevated pacing threshold. System-related causes are common in the perioperative period, especially lead dislodgement. An otherwise sufficient stimulus will fail to capture if it occurs in the physiologic refractory period of a spontaneous depolarization. This "functional failure to capture" may occur as a result of undersensing (**Fig. 36-18**) or asynchronous pacing.

Failure to Pace

Failure to output an appropriate pacing stimulus is most commonly due to oversensing of physiologic (**Fig. 36-19**) or nonphysiologic signals, which results in inhibition of pacing output. (See also later discussion of oversensing in ICDs.) Rarely, it may be caused by failure of the output circuit in the pulse generator or an open circuit (e.g., a lead fracture or a loose set screw). The combination of failure to capture and failure to pace usually indicates a pacing system problem as opposed to a physiologic problem.

Crosstalk is a specific form of oversensing in which the pacing stimulus is sensed in the opposite chamber. Clinically, the most important form of crosstalk is oversensing of the atrial pacing stimulus on the ventricular channel, which results in inhibition of ventricular pacing in a patient with AV block (see **Fig. e36-5**). It is minimized by ventricular blanking after atrial pacing. Settings that promote crosstalk include high atrial output, ventricular sensing parameter

TABLE e36-3 Non-Device-Related Interventions to Reduce Shocks in Patients with Implantable Cardioverter-Defibrillators

	SHOCKS FOR VT/VF	SHOCKS FOR AF/ SVT
General Cardiac Care		
Prevent metabolic abnormalities (e.g., K^+)	X	
Prevent ischemia	X	
Optimize heart failure therapy	X	X
Maximize the beta blocker dose*	X	X
Non-Device-Related Therapy for Arrhythmias		
Antiarrhythmic drugs (sotalol, amiodarone)	X	X
Catheter ablation	X	X
Minimize Proarrhythmia		
From drugs	X	
From pacing	X	X
Lifestyle		
Minimize triggers in susceptible patients	X	X

**TABLE 36-4 Common Causes of Pacemaker Problems**

Failure to Capture
Pacing output below threshold
Changes at electrode-myocardial interface
Output programmed below threshold
Lead dislodgement
Lead insulation failure or conductor fracture
Connection problem between the header and lead
Functional failure to capture (undersensing or asynchronous pacing)
Failure to Pace
Corrected by a magnet or programming to the asynchronous mode
Oversensing of physiologic or nonphysiologic signals
Not corrected by a magnet or programming to the asynchronous mode
Failure in the pulse generator
Lead conductor fracture
Connection problem between the header and lead
Pacing at a Rate Not Consistent with the Programmed Rate
Shorter than expected escape interval—undersensing
Longer than expected escape interval—oversensing
Battery depletion
Unanticipated Rapid Pacing
Pacemaker-mediated tachycardia
Inappropriate ventricular tracking of rapid sensed atrial rates, electromagnetic interference, or myopotentials
Sensor-driven pacing unrelated to patient activity

programmed to a very sensitive value, and short duration of ventricular blanking after atrial pacing. Pacemakers have features to prevent crosstalk, including ventricular blanking after atrial pacing and triggered ventricular pacing in response to a sensed event in the AV interval.

Lead or header connector problems can cause oversensing of non-cardiac signals (see **Fig. 36-20F** for an ICD example). Lead insulation failures may be manifested as low pacing impedance (**Fig. e36-6B**), and conductor fractures may cause abrupt increases in pacing impedance (**Fig. e36-6D, E**). However, both insulation failures and fractures may be associated with oversensing and normal impedance (**Fig. e36-6A**) because sensing is continuous whereas impedance is measured only intermittently. Header connector problems occur in various forms, including failure to insert the lead fully into the connector block and failure to tighten the set screw. Their oversensing signals are indistinguishable from those associated with fractures, but their impedance trends may differ (**Fig. e36-6C**).

Pacing at a Rate Not Consistent with the Programmed Rate

Pacing with a shorter than expected escape interval usually indicates undersensing (see **Fig. 36-18**). Pacing with a longer than expected escape interval usually indicates oversensing (**Fig. 36-21**, left panel). Like oversensing, undersensing can be related to the pacing system, the patient, or patient-system interactions. Premature complexes can have different local EGMs than normal beats do and may not be sensed even if sensing of normal beats is reliable. A pacing system that undersenses only during premature beats rarely requires revision.

Consistent pacing at a rate slower than the programmed lower rate limit generally indicates either oversensing of a constant signal during each cardiac cycle (most commonly T wave oversensing; **Fig. 36-21**, left panel) or battery depletion.

Unanticipated Rapid Pacing

Rapid pacing, usually at or near the upper rate limit, may be caused by a pacemaker-mediated tachycardia or inappropriate ventricular tracking of rapid sensed atrial rates. Most commonly, pacemaker-mediated tachycardia occurs when the pacemaker functions as the

antegrade limb of an AV reentrant tachycardia and the normal conduction system functions as the retrograde limb (see **Fig. e36-4**). Sensor-driven, pacemaker-mediated tachycardia occurs if the sensor increases pacing rates in response to signals that are unrelated to patient activity, such as an accelerometer responding to vibrations in a helicopter or a minute ventilation sensor responding to an asthma attack. High sensed atrial rates can be caused by nonphysiologic atrial tachyarrhythmias or atrial oversensing (e.g., pectoral myopotentials or electromagnetic interference). If mode switch is not programmed or fails to occur, dual-chamber pacemakers will track these nonphysiologic sensed atrial rates near the upper rate limit. Endless-loop tachycardia or tracking of high sensed atrial rates can be terminated by programming to a nontracking mode. Sensor-driven, pacemaker-mediated tachycardia can be terminated by altering the rate-response parameters or programming to rate-response off.

Adverse Consequences of Appropriate Sensing and Capture

Pacemaker syndrome, described previously, is due to loss of AV synchrony. Extracardiac stimulation can occur as a result of unwanted stimulation from the pocket or cardiac stimulation from a lead close to the phrenic nerve, diaphragm, or intercostal muscle. Rarely, normal pacemaker function can be proarrhythmic, especially if normal function results in pauses causing short-long-short sequences in the ventricle, thereby initiating pause-dependent VT/VF. Proarrhythmia is more common in ICD patients than in pacemaker patients (**Fig. e36-7**). Because short-long-short sequences are common during programming, an external defibrillator should be available during programming of pacemaker patients whose underlying rhythm is slow. Rarely, rapid pacing during threshold testing may cause VT.

Misinterpretation of Normal Pacemaker Function

Historically, fusion and pseudofusion beats on the ECG have been a source of confusion. Fusion indicates that depolarization occurs partially as a result of intrinsic activation and partially as a result of capture from the pacemaker stimulus (**Fig. 36-22**). Pseudofusion indicates that the pacemaker stimulus does not alter the intrinsic QRS morphology on the surface ECG. This occurs after normal depolarization of the ventricles has already started and it is therefore not altered by the electrical stimulus. At times the surface ECG may not permit determination of the chamber paced. For example, atrial undersensing during AF results in functional failure of atrial capture but can be misinterpreted as failure of ventricular capture.

Contemporary pacemakers have features that may not be inferred from the basic timing cycles without detailed knowledge of specific programming. As noted previously, a common cause of confusion is related to algorithms that promote intrinsic AV conduction in dual-chamber pacemakers (see **Fig. 36-13**).

Implantable Cardioverter-Defibrillators

For ICDs, the most common troubleshooting issues include determination of the reason for shocks, ineffective therapy, and failure to deliver therapy.

Troubleshooting Shocks

Figure 36-23 summarizes a three-step approach to a patient with a shock based on clinical features and stored device data: (1) determine whether the shock was delivered in response to oversensing or to a tachycardia, (2) determine whether the tachycardia was VT/VF or SVT, and (3) determine whether the VT might have terminated spontaneously or should have been treated with ATP. The first step in troubleshooting shocks is to determine whether therapy was delivered in response to oversensing or to a tachycardia.

Oversensing

Inappropriate shocks can occur in the absence of tachycardias when nonarrhythmic physiologic or nonphysiologic signals are oversensed and detected as arrhythmias.^{3,13} Nonphysiologic signals are usually extracardiac. Physiologic signals can be intracardiac (P, R, or T

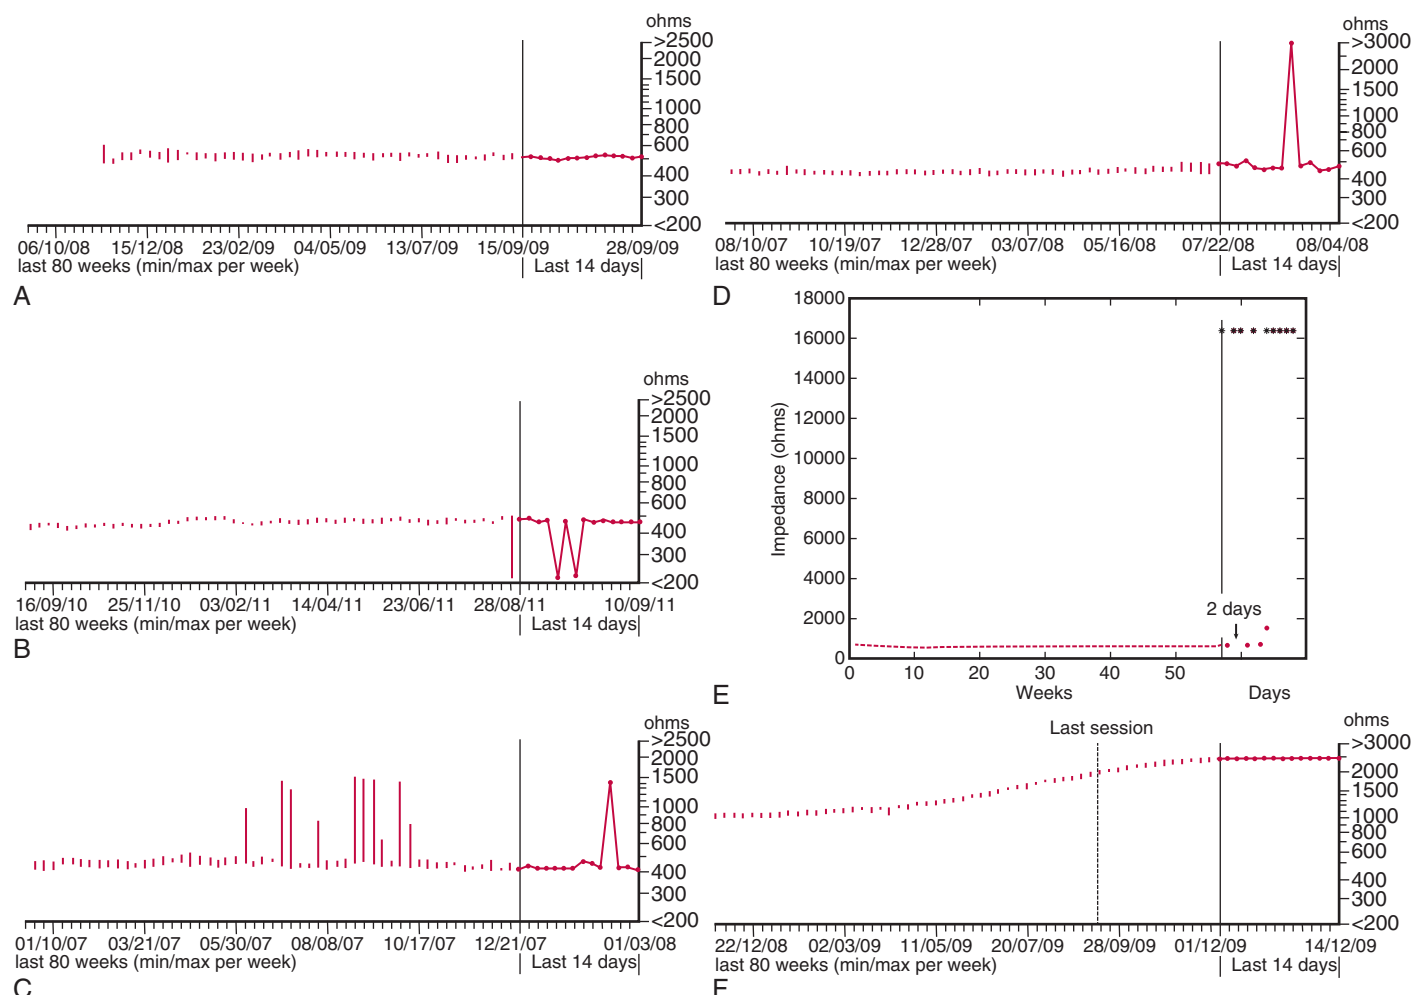

FIGURE e36-6 Impedance trends for pace-sensing electrodes. To the *left* of the longest vertical line, data are displayed as vertical bars connecting weekly maximum and minimum impedance values. To the *right*, black points indicate daily values. **A**, Normal impedance trend. Although this trend occurred in a normal lead, normal trends may occur with conductor fractures and insulation failures. **B**, Lead insulation failure showing a late abrupt fall in impedance. Highly variable impedances are seen beginning approximately 4 months after implantation followed by approximately a 2-month return to baseline between early October and December 2007. **C**, Lead conductor fracture with a late, abrupt increase in impedance to highest reported value (>3000 Ω). **D**, Engineering-level display of stored data for another lead conductor fracture. Although the programmer displays impedance only up to a maximum value of 3000 Ω, impedance is measured up to 16,000 Ω. A late abrupt increase in impedance to an open-circuit value is diagnostic of a conductor fracture. **E**, Gradual increase in impedance in a normally functioning lead, thought to be due to changes at the electrode-myocardial interface.

FIGURE e36-7 Pacing-induced proarrhythmia seen on an electrocardiographic tracing from a patient with a pacemaker programmed to VVI at approximately 70 pulses/min. There is a longer V-V interval representing oversensing (*); a subsequent pacing spike occurs with failure to capture (**); and in the terminal portion of the tracing, VT develops and the pacemaker does not sense the tachyarrhythmia. Pacing artifacts can be seen during VT, labeled V-U (ventricular undersensing).

25.0 mm/sec

25.0 mm/sec

FIGURE 36-17 Continuous recording shows failure to capture. Right atrial, right ventricular, and ECG channels are shown. A marker channel is superimposed on the atrial channel. The fifth ventricular paced event is not captured. This is followed by 2:1 AV conduction, which continues into the lower panel.

FIGURE 36-18 Ventricular undersensing: telemetry with a surface ECG (top), atrial EGM (middle), and ventricular EGM (bottom). Markers correspond to the ventricular channel. There are six ventricular events but only three with marker annotation. The first ventricular event is neither sensed nor annotated. The second ventricular event is paced (V). The third is intrinsic (R). The fourth is not sensed and is followed approximately 360 milliseconds later by a paced event (V) that corresponds to an escape interval timed from the event marked "R." Undersensing results in escape intervals shorter than the programmed escape interval. The final intrinsic event is not sensed.

waves) or extracardiac (myopotentials) (see Fig. 36-20A-C). This contrasts with the manifestation of oversensing in pacemakers as failure to pace or pacing slower than the lower rate limit. In ICD patients who require pacing, oversensing is also manifested as in pacemaker patients.

Oversensing of physiologic intracardiac signals can result in two device-detected R waves for each cardiac cycle. P wave oversensing and R wave double counting are manifested as alternating cycle lengths of sensed R-R intervals and alternating morphologies.¹⁴ P wave oversensing can occur if the distal coil of an integrated bipolar lead is too close to the tricuspid valve. R wave double counting occurs if the duration of the sensing EGM exceeds the ventricular blanking period of 120 to 140 milliseconds. T wave oversensing may occur in the setting of normal-amplitude or low-amplitude R waves. Whereas oversensing of native T waves causes inappropriate detection of VT/VF, oversensing of paced T waves causes bradycardia pacing at a slower than programmed rate.

When extracardiac signals are oversensed, the isoelectric baseline is replaced by high-frequency "noise" signals that have no fixed relationship to the cardiac cycle (Fig. e36-8; also see Fig. 36-20D-F), analogous to artifact on the surface ECG. External electromagnetic interference is usually continuous. Signal amplitude is greater on a

FIGURE e36-8 Stored EGM showing the characteristics of intermittent oversensing caused by fracture of a lead. The pace-sensing (V_{Tip}-V_{Ring}), high-voltage (RV Coil-Can), and marker channels are shown. VS, TS, and FS = intervals in the sinus, VT, and VF zones, respectively. FD = detection of VF. The **upper and lower panels** are continuous. The pace-sensing channel shows intermittent, high-frequency oversensing of nonphysiologic noise characteristic of a lead fracture or header connector problem. Characteristics of these nonphysiologic signals include high frequency, high variability, periods of normal EGMs (intermittency), and amplifier saturation. However, conductor fractures may be accompanied by atypical oversensing. The high-voltage channel shows only normal EGMs, which indicates that the conductor to the right ventricular shock coil is intact.

FIGURE 36-19 Ventricular oversensing of external electromagnetic interference results in inhibition of pacemaker output in a patient with longstanding AF and complete heart block. Atrial bipolar, right ventricular (RV) integrated bipolar, and dual-chamber marker channels are shown. Nonphysiologic rapid signals have much greater amplitude on the ventricular channel because of its larger sensing dipole despite the fact that gain is lower on the ventricular channel. Nonphysiologic signals show a repetitive pattern of amplitude modulation approximately every 120 milliseconds.

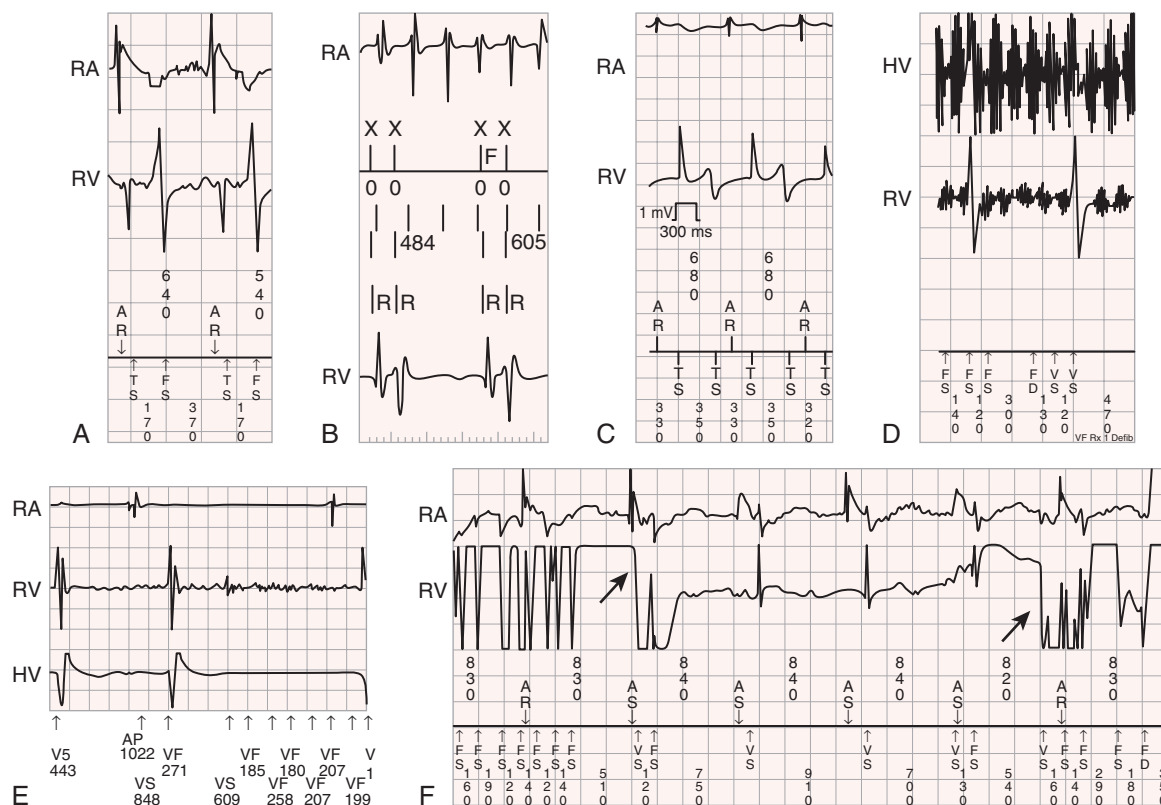

FIGURE 36-20 Types of oversensing resulting in inappropriate detection of VT or VF. **A-C**, Oversensing of physiologic, intracardiac signals. **D-F**, Oversensing of extra-cardiac signals. **A**, P wave oversensing in sinus rhythm from an integrated bipolar lead with the distal coil near the tricuspid valve. **B**, R wave double counting during conducted AF in a biventricular sensing ICD. **C**, T wave oversensing in a patient with a low-amplitude R wave (note the mV calibration marker). **D**, Electromagnetic interference from a power drill has higher amplitude on a widely spaced high-voltage EGM than on a closely spaced true bipolar sensing EGM. **E**, Diaphragmatic myopotential oversensing in a patient with an integrated bipolar lead at the RV apex. Note that the noise level is constant but oversensing does not occur until automatic gain control increases the gain sufficiently, approximately 600 milliseconds after the sensed R waves. **F**, Lead fracture noise results in intermittent saturation of the amplifier range as denoted by the arrows. HV = high-voltage electrogram; RA = right atrium; RV = right ventricular sensing electrogram. (From Swerdlow CD, Friedman P: Implantable cardioverter-defibrillator. In Zipes D, Jalife J [eds]: *Clinical Aspects in Cardiac Electrophysiology: From Cell to Bedside*. 6th ed. Philadelphia, WB Saunders [in press].)

FIGURE 36-21 Classification of T wave oversensing. During pacing (**left panel**), T wave oversensing may cause a pause. From top to bottom in the left panel are shown the surface ECG, atrial EGM, ventricular EGM, and marker annotations. The oversensed T wave is indicated with an arrow on the ventricular EGM. The **middle panel** shows T wave oversensing with a very small R wave-to-T wave ratio, in this case caused by small R waves and normal-sized T waves. From top to bottom are the atrial EGM, near-field ventricular EGM, and markers. Reprogramming options are limited in this situation, and lead revision is often necessary. It is important that the near-field ventricular EGM be reviewed (as opposed to the far-field EGM) because this represents the signal that the ICD uses for rate detection. The **right panel** shows T wave oversensing in the setting of a large R/T ratio; this is typically corrected with device reprogramming. From top to bottom are the ventricular near-field EGM and markers. (From Swerdlow CD, Friedman PA: *Advanced ICD troubleshooting: Part I. Pacing Clin Electrophysiol* 28:1322, 2005.)

FIGURE 36-22 Three-channel tracing from an ambulatory monitor. The first QRS is intrinsic. The second and fourth beats represent fusion. The third beat is pseudofusion; that is, the underlying morphology is almost identical to the intrinsic QRS. The final QRS represents paced depolarization.

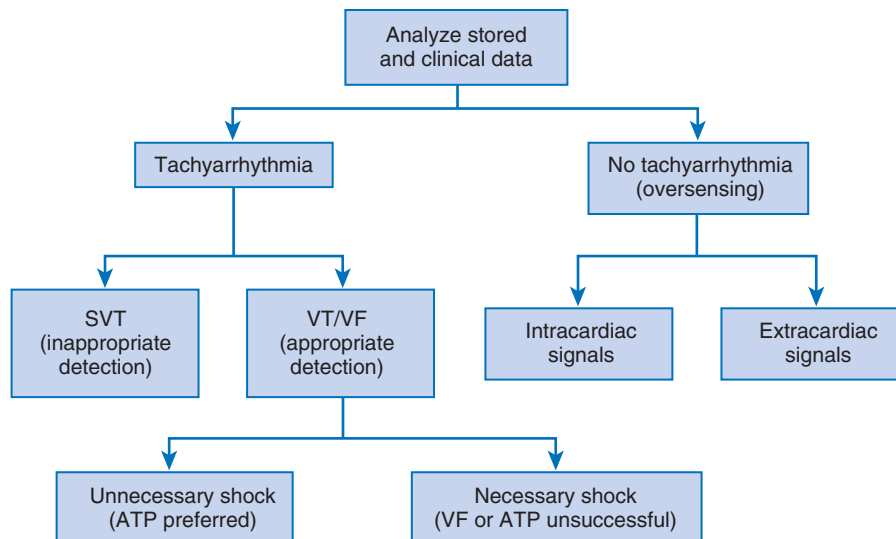

FIGURE 36-23 Approach to a patient with ICD shocks. See text for details. (With permission from Swerdlow CD, Friedman P: *Implantable cardioverter-defibrillator*. In Zipes D, Jalife J [eds]: *Clinical Aspects in Cardiac Electrophysiology: From Cell to Bedside*. 6th ed. Philadelphia, WB Saunders [in press].)

high-voltage EGM recorded from widely spaced electrodes than on a sensing EGM recorded from closely spaced electrodes. Oversensing because of lead or connector (header, adapter, or set screw) problems is intermittent, occurs only during a small fraction of the cardiac cycle, and may be associated with abnormal pacing-lead impedance. It can be limited to the sensing EGM and can saturate the amplifier range. Lead-related oversensing is the most important, both because the ICD system may not deliver pacing or necessary shocks and because an inappropriate shock into a faulty lead can be sufficiently strong to induce VF (if it is applied in the vulnerable period) but insufficient to defibrillate it. Myopotential oversensing has variable duration. Pectoral myopotentials are more prominent on the high-voltage EGM, whereas diaphragmatic myopotentials are more prominent on the sensing EGM.

Ventricular Versus Supraventricular Tachycardia

If stored EGMs indicate that a shock was delivered in response to a true tachycardia, the second step in diagnosis is to determine whether the rhythm is VT or SVT. Established principles of ECG and EGM analysis usually lead to the correct diagnosis (**Fig. e36-9**; see also **Chapter 34**).^{15,16}

For single-chamber ICDs, diagnosis is based on analysis of onset of the tachycardia and the morphology and regularity of the ventricular EGM. A real-time reference sinus EGM should be recorded with the patient in the same posture in which the episode occurred to facilitate analysis of EGM morphology. For dual-chamber ICDs, analysis of the chamber of onset, atrial and ventricular rates, and AV relationships improves diagnostic accuracy. Inappropriate therapy for SVT can be reduced by programming VT and VF detection rates and duration, optimal programming of SVT-VT discriminators, appropriate use of beta blockers and antiarrhythmic drugs for SVT, and catheter ablation of SVT. See **Figures 36-24** and **e36-10 through e36-12** for examples.

Nonsustained Ventricular Tachycardia

Shocks or aborted shocks in response to self-terminating VT can be prevented by increasing the duration for detection or altering specific programming related to how ICDs check to determine whether VT/VF is still present during and after capacitor charging ("confirmation or reconfirmation"; see **Fig. e36-10**).

Unnecessary Shocks for Sustained Ventricular Tachycardia

The frequency of sustained VT can be reduced by treatment with beta blockers, antiarrhythmic drugs,¹⁷ or catheter ablation. Most

monomorphic VTs can be terminated by painless ATP (see **Figs. 36-16** and **e36-10**), and multiple studies have shown that the frequency of shocks for VT can be reduced by programming ATP for monomorphic VT unless it is specifically contraindicated because of repeated acceleration of VT to faster VT or VF.

Approach to the Patient Experiencing an Implantable Cardioverter-Defibrillator Shock

If a patient experiences single or infrequent shocks, the ICD should be interrogated within 24 to 48 hours unless the necessary clinical information is available from a remote monitoring system. Frequent or repetitive shocks constitute an emergency. If a patient receives inappropriate repetitive shocks caused by SVT or oversensing during sinus rhythm, VT/VF detection can be disabled by a programmer or magnet. Repetitive shocks for VT can be caused by recurring episodes of VT after successful shock termination of VT (VT storm, cluster shocks) or by multiple unsuccessful shocks for a single episode. Therapeutic approaches differ. VT storm can be caused by acute ischemia, exacerbation of heart failure, metabolic abnormalities (e.g., hypokalemia, amiodarone-induced hyperthyroidism), and drug effects (e.g., proarrhythmia, change in prescribed drugs, or noncompliance). Diagnosis of acute coronary syndromes during VT storm is difficult because multiple shocks can cause changes in repolarization and elevations of troponin I. Therapy may include reversal of the precipitating cause, beta blockers, antiarrhythmic drugs (e.g., sotalol, amiodarone), and catheter ablation. Care providers must address the psychosocial issues related to shocks in addition to the medical issues (see **Follow-Up**, later).

Unsuccessful Shocks

Because the success of defibrillation is probabilistic, occasional shocks fail, but failure of two maximum-output shocks to convert VF is rare if the safety margin is adequate. If an ICD classifies a shock as unsuccessful, stored EGMs should be reviewed to determine whether the shock was delivered during true VT/VF and whether the shock actually terminated the VT/VF but did not recognize that the arrhythmia terminated. For example, ICDs misclassify effective therapy as ineffective if VT/VF recurs before the ICD determines that the VT/VF episode has terminated or if the postshock rhythm is SVT in the VT rate zone (e.g., catecholamine-induced sinus tachycardia or shock-induced AF).

Shocks from chronic ICD systems that defibrillated reliably at implantation may fail to terminate true VT or VF because of patient-related or ICD system-related reasons. In chronically implanted systems, most patient-related causes of unsuccessful shocks can be

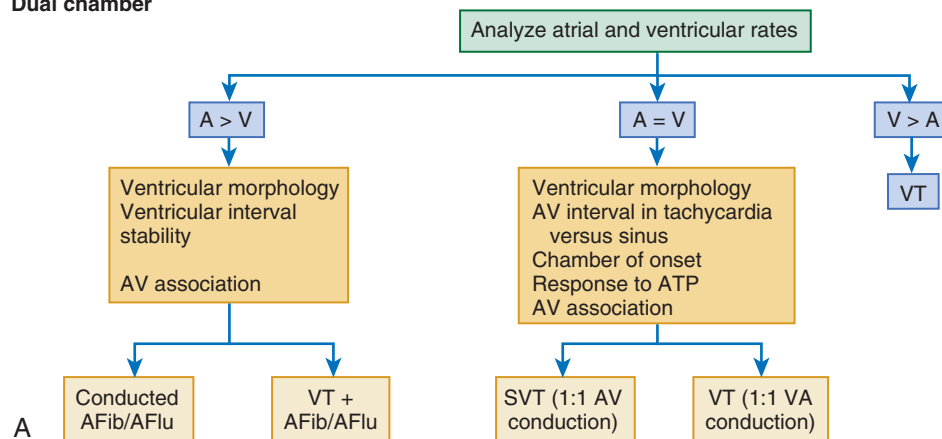

FIGURE 36-24 Dual-chamber EGM showing polymorphic VT with AV dissociation treated with shock. The atrial EGM, high-voltage ("shock") EGM, and dual-chamber marker channel are shown. The arrowhead denotes shock, designated by CD (charge delivered) on the marker channel. After the shock the atrial rhythm is sinus with premature atrial complexes; the ventricular rhythm is biventricular paced (BV) with premature ventricular complexes in the sinus rate zone (VS). The second BV beat (BV/VS) has a slightly shorter paced AV delay (110 versus 130 milliseconds) than first BV beat does because a premature ventricular complex occurs during the AV delay and triggers "safety pacing," a feature that reduces crosstalk inhibition.

Dual chamber

Single chamber

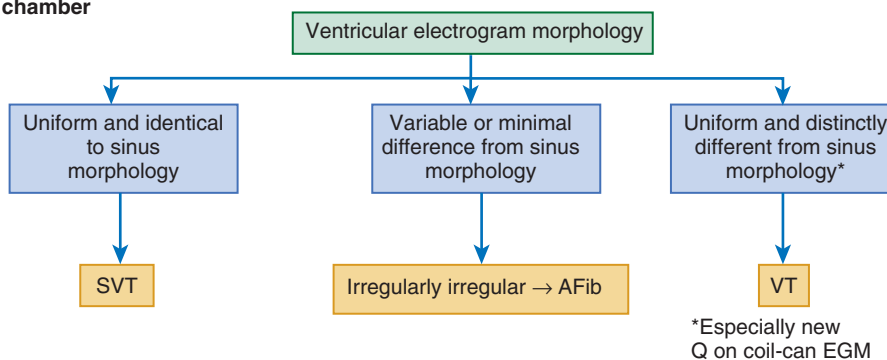

FIGURE e36-9 Method for analysis of stored EGMs in dual-chamber ICDs **(A)** and single-chamber ICDs **(B)**. AFib = atrial fibrillation; AFlu = atrial flutter. See text for details. (Modified from Swerdlow C, Friedman P: *Advanced ICD troubleshooting: Part I. Pacing Clin Electrophysiol* 28:1322, 2005.)

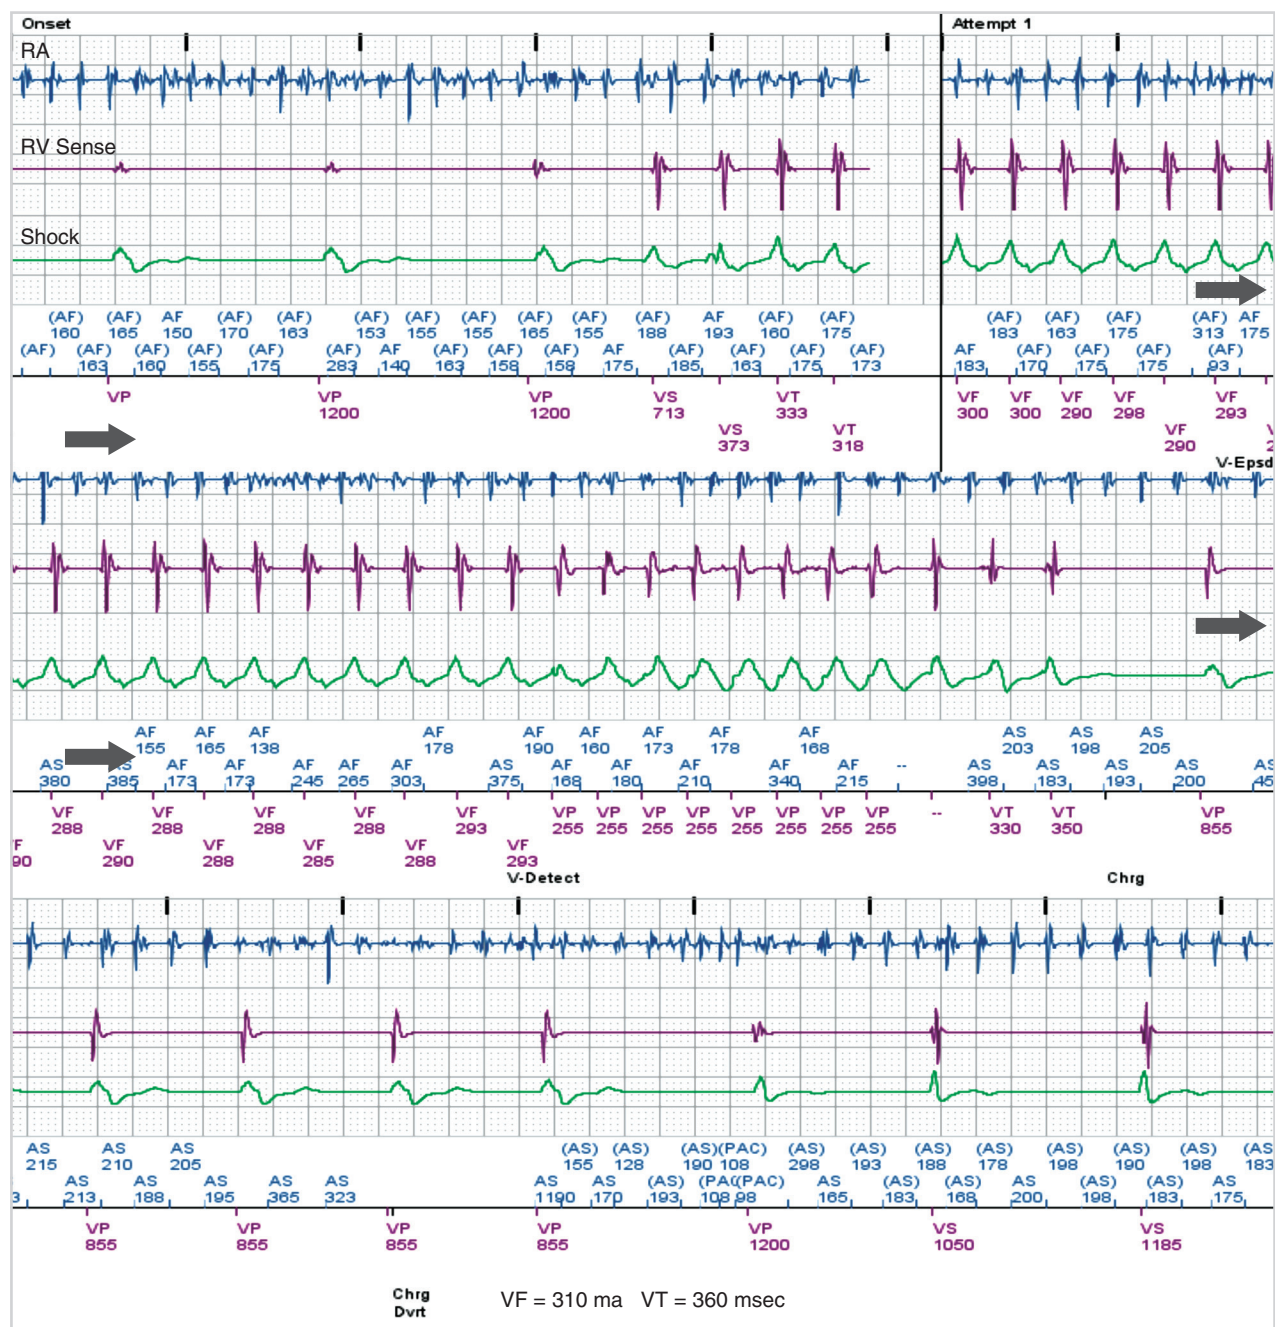

FIGURE e36-10 Interpretation of an ICD EGM. The continuous stored EGM shows atrial (RA), near-field integrated bipolar (RV Sense), and far-field (Shock) EGMs. The dual-chamber marker channel displays atrial intervals above and ventricular intervals below the line. The atrial rhythm throughout is AF (marker channel). The first three ventricular intervals are paced at 1200 milliseconds (50 beats/min). The fourth beat shows the onset of regular tachycardia, which accelerates to a cycle length of 300 to 290 milliseconds. The vertical line denotes interruption of recording after the onset of tachycardia until just before VF is detected initially (V-Epsd at the end of the top panel). Persistence of device-detected "VF" is confirmed in the middle of the middle panel (V-Detect), followed by ATP in the VF zone, which terminates the tachycardia. ATP is followed by post-therapy pacing for 5 beats at 855 milliseconds (70 beats/min). Because ATP was delivered in the VF zone, the ICD begins to charge as soon as ATP is completed. In the lower panel, "Chrg Dvrt" indicates that the ICD classifies the tachycardia episode as completed, so the charge on the high-voltage capacitors is dissipated. Thus the patient is spared a shock, but the battery loses the corresponding energy. The last two ventricular EGMs in the lower panel represent slowly conducted AF and differ markedly in morphology from tachycardia EGMs. The ICD's classification of this rhythm based on rate alone is "VF." The ICD does not apply SVT-VT discriminators in the VF zone. The physician's classification is monomorphic VT during AF based on an abrupt onset of rapid, regular tachycardia with morphology different from conducted beats during AF. The ICD should be reprogrammed so that this tachycardia is classified in a VT zone and ATP can be delivered without charging.

FIGURE e36-11 Correct classification of rapidly conducted AF by ventricular EGM morphology. The atrial EGM, right ventricular sensing EGM, and dual-chamber marker channel are shown. Most intervals are classified in the VF zone (FS), which is programmed to less than 320 milliseconds. The AF designation at right of the marker channel (red box) indicates that the rhythm is classified as AF. The basis for this classification is shown in the lower panel, which compares the morphology of shock (high-voltage) EGMs during tachycardia (solid lines) with those of a template stored during baseline sinus rhythm (dotted line). Match percentages of 70% or greater between the two EGMs are considered sufficiently close that the rhythm is classified as supraventricular. It is designated as AF based on the atrial rhythm.

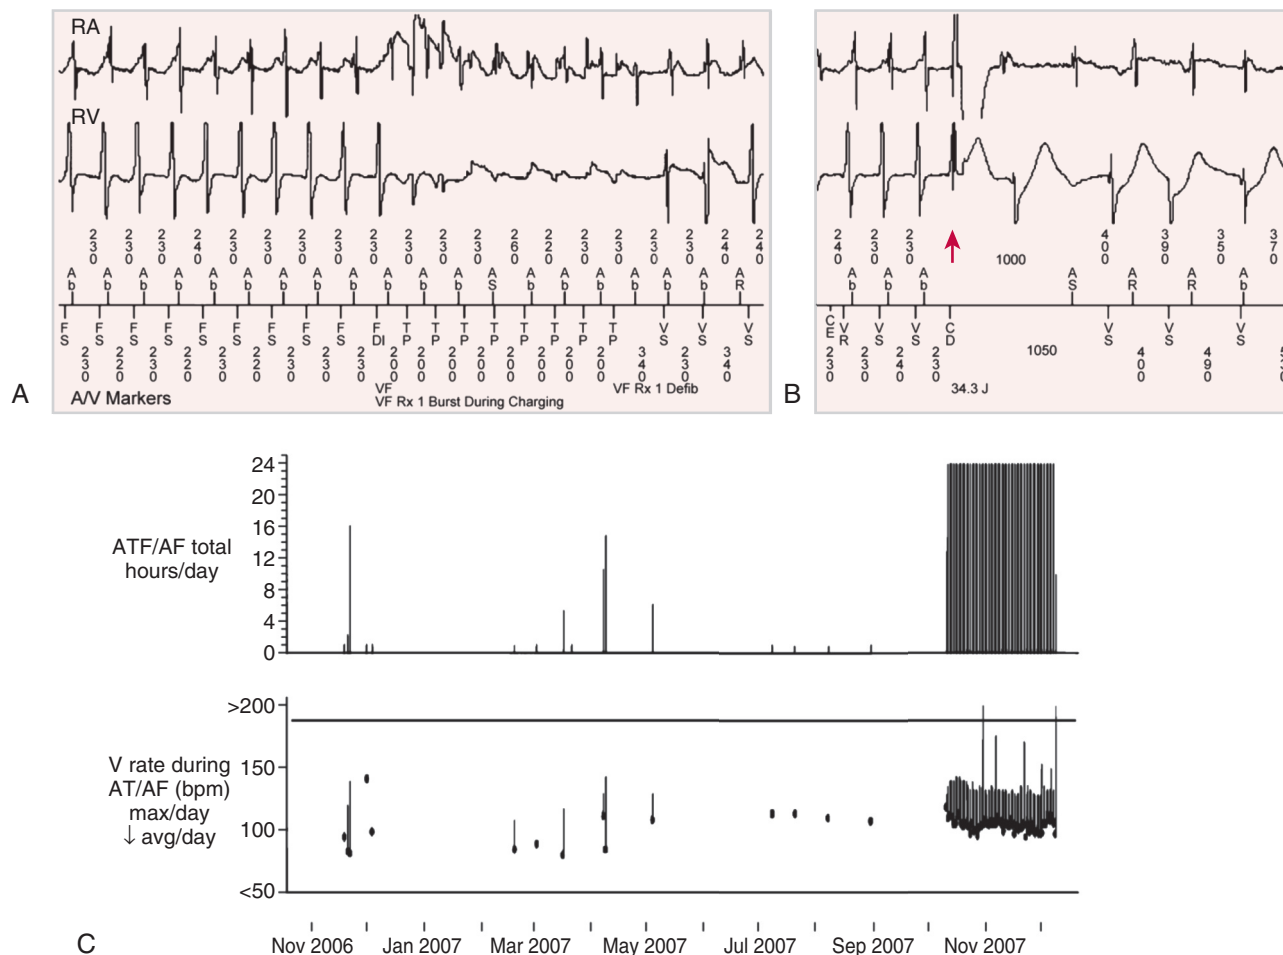

FIGURE e36-12 Inappropriate shock for 1:1 conduction of atrial flutter in an asymptomatic patient with ischemic cardiomyopathy. Right atrial (RA) and right ventricular true bipolar sensing (RV) EGMs are displayed together with a dual-chamber marker channel. **A**, A 1:1, regular tachycardia with a short RP interval and a cycle length of 230 milliseconds detected in the VF zone. Ab = atrial EGM in the postventricular atrial blanking period; FD = detection of VF based on duration criterion; FS = ventricular interval in the VF zone; TP = ATP (during capacitor charging). Ventricular ATP does not terminate tachycardia, but the marker channel shows AV dissociation during ATP, thus permitting a diagnosis of atrial flutter (versus VT with 1:1 VA conduction). **B**, End of charging (CE) followed by confirmation that the tachycardia persists and delivery of a shock (CD, arrow). The shock terminates the atrial flutter and causes distortion of the ventricular EGM after the shock. **C**, Long-term plots show that AF or atrial flutter began approximately 6 weeks before this event and that the ventricular rate approached or exceeded the single-zone detection rate of 187.5 beats/min (320 milliseconds) three times before this shock. If the patient had either audible or wireless remote monitoring alerts activated for persistent AF and/or AF with a rapid ventricular rate, his arrhythmia and/or its rapid ventricular rate would have been detected while he was asymptomatic, and he would not have been exposed to the thromboembolic risk of atrial cardioversion without anticoagulation. (From Swerdlow CD, Friedman P: Implantable cardioverter-defibrillator. In Zipes D, Jalife J [eds]: *Clinical Aspects in Cardiac Electrophysiology: From Cell to Bedside*. 6th ed. Philadelphia, WB Saunders [in press].)

reversed, but most system-related causes require operative intervention (Table e36-4). Failure of multiple high-output shocks to terminate a regular tachycardia suggests sinus tachycardia because monomorphic VT and nonsinus SVT are usually terminated by one or two shocks. Rarely, ICDs misclassify successful shocks or ATP as unsuccessful if VT reinitiates immediately after therapy and before the ICD detects termination of the VT.

Failure to Deliver Therapy or Delayed Therapy

These problems can be due to either ICD programming (including human error) or the ICD system. VT or VF will not be detected if ICD therapy or detection is inactivated, the VT is slower than the programmed detection interval, SVT-VT discriminators diagnose SVT, or sensing is impaired by device-device or intradevice interactions. VF may be undersensed because of combinations of programming (sensitivity, rate, or duration), low-amplitude EGMs, rapidly varying EGM amplitude, drug effects, or postshock tissue changes. Lead, connector, or generator malfunction may also prevent therapy from being delivered.

COMPLICATIONS

Complications can be divided into early surgical complications and late complications related to the patient or pacemaker/ICD system. See Table e36-5.

Implant-Related Complications

Implant-related complications may be related to (1) vascular access, (2) lead placement, (3) pocket integrity, (4) hemodynamics, or (5) infection. Overall, major complications occur in approximately 4% to 5% of new implants¹⁸ and in 2% to 3% of generator changes.¹³

Vascular Access

The first major step in device implantation is establishing venous access for placement of the pacemaker or ICD leads. Access can be complicated by injury to the lungs, vasculature, nerves, or other adjacent structures. Pneumothorax is most commonly seen with subclavian vein access because of its proximity to the lungs. The risk for pneumothorax is almost nonexistent with extrathoracic axillary vein puncture and cephalic vein cutdown. Vascular damage can involve damage to the axillary and subclavian veins and arteries. Less commonly, a combined puncture of one of these vessels and the lungs may lead to hemopneumothorax. In addition to damage to the vascular tree, inadvertent entry into the arterial system may lead to placement of a lead retrogradely across the aorta into the left ventricle. There are numerous reports of placement of a lead chronically in the left ventricle via this approach. There is also a risk for entry into the left atrium by inadvertent access from the right atrium via a patent foramen ovale. An unexplained stroke in a pacemaker patient should prompt echocardiographic examination of the position of the atrial and ventricular leads to confirm they are not in left-sided chambers.

Lead Placement

The most common complication arising from lead placement is lead dislodgement, which usually requires lead revision. Sometimes the tip of the lead moves minimally, a complication called “microdislodgement,” which may increase the pacing threshold but might not require revision. Cardiac perforation may result in significant pericardial effusion or cardiac tamponade, but this does not occur often because as the lead is pulled back into the heart, the heart tissue closes over the perforation. Lead placement can also result in phrenic nerve stimulation leading to uncomfortable diaphragmatic contractions. This is particularly common with leads placed in lateral branches of the cardiac venous system because the left phrenic nerve runs over that region. Right atrial pacing along the free wall may stimulate the right phrenic nerve. Stimulation of intercostal muscles may be a sign that the tip of the lead or screw has passed through a

thin region of the right ventricle. Rarely, microperforation of a screw-in right atrial lead may result in a right-sided pneumothorax or hemopneumothorax because of the proximity of the right lung to the right atrial wall. Lead placement can cause extrasystolic beats, called “tip extrasystoles,” because of mechanical effects of the tip of the lead against the myocardium, but this problem usually resolves within 24 hours and rarely requires lead repositioning. Rarely, right ventricular leads may cause a clinically significant increase in tricuspid regurgitation. Clinically important lead-related tricuspid regurgitation is rare but may require valve replacement or repair, particularly if the lead perforates one of the tricuspid valve leaflets. Chest pain after intracardiac lead placement may indicate pericardial irritation or pericarditis. Lead placement may also cause thrombosis of the subclavian or axillary vein and lead to arm edema. Usually, elevation of the arm with or without anticoagulation results in considerable improvement. Superior vena cava thrombosis is rare but more serious. It may necessitate lead extraction or rarely surgery. A loose set screw or inadequate connection of the lead terminal pin to the header may result in oversensing of nonphysiologic signals. Magnification of the generator via radiography may detect a terminal pin that is not fully inserted into the header (Fig. e36-13).

Device-Related Infection

Device infections may occur early after implantation or be delayed. Early infections are usually caused by skin organisms such as *Staphylococcus* or *Streptococcus*. Antibiotic prophylaxis given immediately before device implantation reduces the risk for perioperative infection.¹⁴ Late infections may be caused by intraoperative contamination with indolent organisms or by hematogenous infection of the leads or pulse generator. Erosions that occur early after implantation are often related to acute hematomas. Late “erosions” generally indicate indolent infection. Generator pocket infections commonly occur after a generator change and may be manifested as pain, erosion, erythema, or purulent drainage. Standard treatment of device-related infection is removal of the generator, extraction of the entire lead system, and treatment with antibiotics. If bacteremia or other evidence of systemic infection is present, intravenous antibiotic therapy is indicated for 4 to 6 weeks. Transthoracic and transesophageal echocardiograms are frequently used to identify vegetations on leads. Septic pulmonary emboli may be the first indication of device infection. System infections may be caused by transient bacteremia, particularly within the first several months after initial device implantation. Late infections may be triggered by traumatic injury to the pocket or late hematoma formation.

FOLLOW-UP

Remote Management Technology

Remote follow-up of older pacemakers was performed via analog, transtelephonic systems to determine battery status and evaluate capture and sensing. The convergence of Internet technology, “wireless” pacemaker and ICD telemetry, and enhanced device diagnostics has greatly improved outpatient management by permitting the device to function as a node in a medical informatics network.^{19,20} Remote management includes remote follow-up (scheduled transmissions), patient-initiated remote transmissions for symptomatic events, and remote monitoring (automatic unscheduled transmissions based on prespecified device alerts).

In devices with short-range telemetry, patients initiate transmissions by holding an inductive wand over the pulse generator. The wand connects to a modem, which transmits data over the Internet. ICDs with longer-range radiofrequency transmitters (“wireless telemetry”) transmit stored data automatically to a local hub, which then resends it over the Internet. This permits daily transmission of device status, including alerts triggered by device status, VT/VF, or device-based monitoring of comorbid conditions. Data from the device are then transmitted to a secure server and subsequently to the health care professional (Fig. 36-25).

TABLE e36-4 Causes of Unsuccessful Implantable Cardioverter-Defibrillator Shocks

Misclassified Therapy
VT/VF recurs before the device determines that the VT/VF episode has terminated
Failure to terminate SVT (e.g., sinus tachycardia)
Postshock rhythm is SVT in the VT rate zone
Patient-Related Factors
Metabolic (hyperkalemia)
Ischemia
Progression of heart failure
Some antiarrhythmic drugs (e.g., amiodarone, type IC)
Pleural or pericardial effusions
Device System–Related Reasons
Insufficient programmed shock strength
Battery depletion
Failure of generator component or lead
Incorrect device-lead connection
Lead dislodgment
Delayed detection resulting in a prolonged episode that increases the shock strength required

TABLE e36-5 Complications of Pacemakers and Implantable Cardioverter-Defibrillators

Vascular Access
Pneumothorax
Hemopneumothorax
Vascular perforation
Placement of a lead into the left atrium or left ventricle via a patent foramen ovale
Placement of a lead into the subclavian artery and retrograde across the aortic valve
Lead Placement
Lead dislodgement
Lead microdislodgement
Cardiac perforation with hemopericardium (possible cardiac tamponade)
Extracardiac stimulation*: phrenic nerve, intercostal muscle, left hemidiaphragm
Tricuspid regurgitation
Subclavian or axillary vein thrombosis
Loose set screw
Device-Related Infection
Erosions
Pocket infection
Endocarditis
Bacteremia

*May indicate perforation by the tip of the lead or screw.

FIGURE e36-13 Intraoperative fluoroscopic images of a cardiac resynchronization ICD show incomplete insertion of the right ventricular pace-sensing lead pin into the header. The ICD has been removed from the pocket to enhance image quality. Before revision, the lead connector pin was not advanced completely into the header (arrow). The proximal connection between the ring electrode and the header was intermittent, which resulted in high impedance and oversensing causing pauses in the paced rhythm. After revision, the right ventricular electrode is advanced completely into the header. (From Swerdlow CD, Gillberg JM, Khairy P: Sensing and detection. In Ellenbogen KA, Kay GN, Lau CP, Wilkoff BL (eds): *Clinical Cardiac Pacing, Defibrillation, and Resynchronization Therapy*. 4th ed. Philadelphia, WB Saunders, 2011, pp 56-126.)

FIGURE 36-25 Remote monitoring of pacemakers and ICDs. The cartoon illustrates the function of a remote monitoring network. Device diagnostics and EGMs are transmitted to a bedside monitor or wearable cellular unit that retransmits the data to a central server. The server prioritizes the data and sends the formatted report to the patient's health care provider. Continuous EGMs at the right show an example of a patient-initiated transmission that was reviewed from home within minutes of being sent by one of the authors (CDS). It shows a pause-dependent polymorphic VT that required two shocks for termination (red boxes on the marker channel). The patient's internist had recently increased the dose of diuretics, and the serum potassium concentration was 2.7 mEq/liter. RV tip-ring = the electrogram recording between the tip of the lead and the ring electrode on the lead; RV coil-can = the electrogram recording between the coil in the lead and the can of the ICD.

Management of Device Status and Ventricular Tachycardia/Fibrillation

Remote monitoring permits identification of an increased frequency of nonsustained VT or asymptomatic sustained VT terminated by ATP. It also permits early diagnosis of device system problems, including those related to the pulse generator—premature battery depletion or high-voltage circuitry failure—and those related to lead integrity. Detection of lead-related problems has been improved by diagnostics that alert for the rapid nonphysiologic oversensing and abrupt changes in measured impedance that are characteristic of lead- or

connector-related problems. Patient-initiated transmissions permit rapid diagnosis when patients experience symptoms that may be related to device function, especially suspected ICD shocks.

Monitoring of Comorbid Conditions: Atrial Fibrillation and Heart Failure

Networks developed for remote monitoring of devices can be used to monitor comorbid conditions if relevant data are stored in the device or input into the local hub from another source. AF (see Chapter 38) and heart failure (see Chapter 25) are the primary

comorbid conditions monitored to date because of their prevalence in patients with devices and their burden on health care.

AF is an important comorbidity that can be monitored reliably by devices with an atrial lead.²¹ ICD patients with rapidly conducted AF have an increased risk for inappropriate shocks, and early diagnosis may permit treatment or reprogramming to prevent inappropriate therapy. Early treatment of new-onset, persistent AF may reduce exacerbations of heart failure. The confluence of continuous remote monitoring, device alerts for AF, and rapidly acting oral anticoagulants has motivated investigation of the potential role of devices in the management of anticoagulation. AF is the most common reason for remote-monitoring alerts in ICD patients. In device patients, asymptomatic AF episodes as short as 5 minutes in duration are associated with an increased rate of stroke,²² although it is not clear whether it is causal or merely correlated. Presently, data are insufficient to determine whether continuous device monitoring of patients with infrequent paroxysmal AF might permit safe withdrawal of anticoagulation or intermittent use of short-acting anticoagulants.

Monitoring of heart failure is appealing because it has a high prevalence in ICD and cardiac resynchronization patients, continuous device monitoring is technically feasible, and noninvasive home telemonitoring using a scale and blood pressure cuff reduces the frequency of hospitalizations. Devices collect basic data, including heart rate variability and activity level estimated from the accelerometer, that are used for rate-responsive pacing. The low-power technology in present devices allows measurement of intrathoracic impedance to provide an indirect measure of lung water, which may identify worsening heart failure with sufficient warning to permit therapeutic interventions. Existing technology can also measure endocardial acceleration, which provides an indirect measure of contractility. Other implanted heart failure monitors require special sensors, such as those that measure pressure. Considerations related to special sensors include the need for specialized leads, the relationship between the sensed parameter and heart failure, power consumption, and the frequency of data acquisition. In a different approach, clinical data such as weight and blood pressure are input into the remote-monitoring hub from sources external to the device.

Living with Devices

Psychosocial Issues

Psychosocial issues are greater for ICD patients than for pacemaker patients (see Chapter 86). ICD patients may experience anxiety about shocks, but they might also feel protected from the risk for sudden death. Patients with life-threatening VT or VF have similar quality of life when treated with ICDs or antiarrhythmic drugs, but ICD shocks are associated with reduced quality of life. ICD recipients may benefit from specific interventions such as counseling, education, and support groups. Ongoing research is focusing on specific patient groups that can benefit from specific educational and psychological interventions,²³ as well as acknowledgment of unique stresses on intimate partners of ICD patients.

It is important for health care providers to provide a plan for what ICD patients should do when a shock occurs. Table e36-6 summarizes our approach, which emphasizes patient-initiated remote transmission as the most rapid and efficient approach so that the clinician can obtain the information required for medical decision making. After shocks occur, ICD patients benefit from counseling by a health care professional, including review of what triggered the shock and what intervention has been undertaken to correct or mitigate the underlying problem, estimating the likelihood of future shocks after the intervention, explaining that shocks are one of the challenges of living with heart disease, and usually emphasizing the value of returning to normal activity.

Lifestyle Issues

Driving and Flying

Guidelines²⁴ are based on arrhythmia symptoms and frequency. Patients in whom ICDs are implanted for primary prophylaxis are not

restricted from driving personal cars (as opposed to commercial vehicles). Guidelines recommend that patients refrain from all driving for 6 months after each shock for a ventricular tachyarrhythmia and for 6 months after ICD implantation for secondary prevention. Although most patients resume driving earlier, accidents in ICD recipients occur less often than in the general driving population, and less strict guidelines have been suggested for driving personal cars.²⁵

Participation in Sports

Exercise has unquestioned benefits related to overall health and quality of life (see Chapter 79). However, participation in sports is associated with risk for exercise-induced VT/VF in patients with specific diseases for which ICDs are implanted, such as hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, specific forms of long-QT syndrome, and catecholaminergic polymorphic VT. There is a risk of damaging the generator or lead during contact sports. Swimming is associated with risk for drowning even if VT/VF is treated promptly. Present recommendations restrict ICD patients from competitive and contact sports,²⁶ but these recommendations have been challenged.²⁷ Most experts advise ICD patients against swimming alone.

Drug Interactions

Antiarrhythmic drugs are used in pacemaker patients to prevent AF and in ICD patients to prevent both AF and VT/VF (see Chapters 9 and 35). Randomized controlled trials have reported a reduction in VT/VF when using either sotalol or the combination of amiodarone and beta blockers. However, antiarrhythmic and other drugs have important interactions with devices. See Table e36-7.

Sodium channel-blocking drugs, particularly class IC drugs (e.g., flecainide), may increase pacing thresholds. This effect is especially important during pacing near the upper rate limit or during ATP in ICDs because of use dependence and enhancement of drug-induced sodium channel blockade at faster heart rates. Beta blockers and other drugs that prolong AV conduction may result in increased right ventricular pacing, which may exacerbate heart failure. Hyperkalemia raises pacing thresholds markedly. Patients taking aldosterone antagonists may be particularly at risk, especially if combined with other drugs that raise serum potassium levels.

In ICD patients, antiarrhythmic drugs prescribed for AF may slow the rate of VT. Whenever an antiarrhythmic drug is prescribed, it is important to consider slowing the rate threshold for detection of VT. Drugs may also alter the regularity or morphology of VT. Lidocaine and chronic amiodarone therapy increase the DFT, whereas potassium channel-blocking drugs such as sotalol or dofetilide decrease it.

Electromagnetic Interference

Ubiquitous electromagnetic waves can interfere with pacemakers and ICDs. This might result in temporary or permanent inactivation, inappropriate pacing or inhibition of pacing, and inappropriate detection of VT or VF. Electromagnetic interference is a less of a problem for true bipolar sensing than for integrated bipolar sensing.

Nonmedical Sources of Electromagnetic Interference

Electromagnetic interference is rarely significant in daily life. Cell phones should be held to the contralateral ear and not be carried in the ipsilateral breast pocket. ICD patients may walk through airport metal detectors and electronic article surveillance devices at a normal pace. However, prolonged exposure to electronic article surveillance devices can inhibit pacing and result in inappropriate detection of VT or VF or (in some ICDs) program VT or VF detection off. Some industrial sources pose significant risks, including arc welding, power tools, and large magnets. ICD EGMs and marker channels should be recorded while the patient is operating such equipment, preferably with the ICD in a monitor-only mode.

Medical Sources of Electromagnetic Interference

The two most common medical sources are magnetic resonance imaging (MRI) and surgical electrocautery. Whenever possible,

TABLE e36-6 Patient Plan for Implantable Cardioverter-Defibrillator Shocks*

SHOCKS IN 24 HOURS	RESPONSE
1st Shock	Send remote transmission Call in the morning
2nd Shock	Send remote transmission Call immediately
3rd Shock	Send remote transmission Obtain medical care immediately

*Patients with symptoms other than shocks (e.g., chest pain) should be evaluated for their symptoms.

TABLE e36-7 Common Interactions Between Drugs and Pacemakers/Implantable Cardioverter-Defibrillators

Pacemakers
Effects on Pacing Threshold
Higher threshold Class IC drugs (e.g., flecainide) Amiodarone (chronic effect, especially atrial thresholds)
Lower pacing threshold Glucocorticoids Isoproterenol and epinephrine
Effects on Pacing Burden
Increased atrial pacing burden: drugs that cause sinus bradycardia (e.g., beta blockers, amiodarone, lithium) Increased ventricular pacing burden: drugs that slow AV conduction (e.g., beta blockers, amiodarone)
Implantable Cardioverter-Defibrillators
Frequency of Ventricular Tachycardia or Fibrillation
Increased Antiarrhythmic drugs Drugs with proarrhythmic adverse effects Drugs that interact with proarrhythmic drugs
Decreased Beta blockers Antiarrhythmic drugs (e.g., sotalol, amiodarone)
Consideration for Detection of Ventricular Tachycardia or Fibrillation
VT rate Decrease (most oral antiarrhythmic drugs, especially class IC, amiodarone)
SVT/AF ventricular rate Decrease (beta blockers, amiodarone, sotalol) Increase (class IC drugs, 1:1 conduction of atrial flutter)
Device SVT-VT discrimination algorithms VT interval stability (class IC drugs, amiodarone—more irregular) Altered EGM morphology
Therapy for Ventricular Tachycardia or Fibrillation
Defibrillation energy requirement Increase (class IB, class IC, chronic amiodarone, verapamil) Decrease (sotalol, dofetilide)

cardioversion of AF should be performed through the ICD. When external cardioversion is required, defibrillation pads should be placed at least 8 inches from the pulse generator. Radiofrequency catheter ablation should be performed as far as possible from ICD electrodes, VT/VF detection should be disabled, and inhibition of pacing should be anticipated. Radiation therapy should not be performed over a pacemaker or ICD because it can damage the circuitry of the device. Repositioning of the device to the contralateral side may be required.

MAGNETIC RESONANCE IMAGING. MRI exposes ICD patients to risks as a result of mechanical forces generated by the static magnetic field, heating at the electrode-myocardial interface because of radio-frequency fields, and current induced in the lead by gradient magnetic fields. For these reasons, MRI is relatively contraindicated in patients with devices, except those who have leads and pulse generators approved for conditional MRI use.

MRI has been performed safely in pacemaker and ICD patients by implementing rigorous risk mitigation strategies,²⁸ including before and after interrogation of the imaging device; programming pacemaker-dependent patients to an asynchronous pacing mode; disabling ICD VT/VF detection during scanning; monitoring blood pressure, the ECG, and plethysmography during scanning; limiting the specific absorption rate of tissue during imaging to less than 2 W/kg; and excluding patients with systems implanted within 4 to 8 weeks and those with abandoned leads.

SURGICAL ELECTROCAUTERY. The risk of oversensing of surgical electrocautery (electrosurgery) is greatest when monopolar electrocautery is delivered between a pen and a remote dispersive ground electrode or when the surgical site is in proximity to the device or sensing electrodes.²⁹ For pacemakers, oversensing of electrocautery is more common with unipolar than with bipolar sensing. For ICDs it is more common with integrated bipolar than with true bipolar sensing.

Perioperative Management of Device Patients

Guidelines for perioperative management²⁹ require preoperative determination of pacemaker dependency, device model, type of lead, and plans to use electrocautery (Table e36-8). The arterial pulse must be monitored intraoperatively via an arterial line or plethysmography, and an external defibrillator should be close by. Intraoperative management strategies may include application of a magnet or perioperative reprogramming. When a magnet is placed over a pacemaker, it paces asynchronously. In contrast, a magnet placed over an ICD disables detection of VT/VF but does not alter the pacing mode. Surgical procedures that do not require electrosurgery or for which the wound and dispersive ground pad are both below the umbilicus have a lower risk for electromagnetic interference. Rate-adaptive sensors should be disabled.

Issues Related to Devices at the End of a Patient's Life

An expert consensus statement has addressed the legal and ethical issues related to withdrawal of device therapy to reduce suffering at the end of life (see Chapter 31).³⁰ A patient (or legally defined surrogate decision maker) has the right to request withdrawal of any medical therapy, regardless of whether its withdrawal results in death. Legally, in the United States, deactivation of device therapy is neither physician-assisted suicide nor euthanasia but removal of an unwanted treatment that allows the patient to die naturally from the underlying disease. Physicians should discuss deactivating ICD therapy for VT/VF with patients proactively because 20% of ICD patients receive painful shocks in their last weeks of life. There is less uniform agreement about deactivating pacemakers in pacemaker-dependent patients.

TABLE e36-8 Perioperative Management of Pacemakers and Implantable Cardioverter-Defibrillators

Preoperative Evaluation
<p>Determine whether electrosurgery will be used, operative site in relation to the pulse generator</p> <p>Determine the type and model of device and leads (history, identification card, chest radiograph)</p> <p>Assess whether the patient is pacemaker dependent</p> <p>Assess device function if a full check is not performed within 6 months</p>
Preoperative Preparation
<p>Apply a magnet or reprogram if the surgical site is above the umbilicus</p> <p>Pacemaker and ICD reprogramming: disable rate-responsive pacing, consider increasing pacing output if high-risk surgery, metabolic shifts likely</p> <p>ICD reprogramming: disable VT/VF therapies, reprogram to asynchronous or triggered mode (in ICDs, magnet application does not result in asynchronous pacing)</p> <p>Position a dispersive grounding pad to minimize current near the generator (e.g., apply it to the shoulder contralateral to the device for head and neck surgery)</p>
Intraoperative Management
<p>Monitor the ECG</p> <p>Monitor peripheral pulses (arterial line, plethysmography, pulse oximetry)</p> <p>Transcutaneous pacing and defibrillation pads (anterior-posterior position) for pacemaker-dependent patients if the surgical site permits</p> <p>Use bipolar cautery, an ultrasonic (harmonic) scalpel, or short bursts of electrosurgery</p>
Interrogate Before Discharge from Telemetry If
<p>Device was reprogrammed preoperatively</p> <p>Patient underwent cardiothoracic surgery or other reason likely for power-on-reset</p> <p>Patient experienced clinically significant intraoperative arrhythmia</p> <p>Pacing/sensing thresholds may have changed because of intraoperative hypotension or metabolic abnormalities</p> <p>Device cannot be evaluated within 1 month of the procedure (including remote monitoring)</p>

GUIDELINES

Cardiac Pacemakers and Cardioverter-Defibrillators

Charles D. Swerdlow, Paul J. Wang,
and Douglas P. Zipes

The American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines for the use of cardiac pacemakers, implantable cardioverter-defibrillators (ICDs), and cardiac resynchronization therapy (CRT) were most recently updated in 2008.¹ The ACC, AHA, and European Society of Cardiology (ESC), along with the HRS, collaborated on guidelines for the management of patients with ventricular arrhythmias and the prevention of sudden cardiac death in 2006.² Similar guidelines for cardiac pacing and CRT were published by the ESC in 2007.³

Like other ACC/AHA guidelines, these use the standard ACC/AHA classification system for indications:

- Class I: Conditions for which there is evidence and/or general agreement that the test is useful and effective
- Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test
 - Class IIa: Weight of evidence/opinion in favor of usefulness or efficacy
 - Class IIb: Usefulness or efficacy less well established by evidence/opinion
- Class III: Conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Three levels are used to rate the evidence on which recommendations have been based. Level A recommendations are derived from data from multiple randomized clinical trials, level B recommendations are derived from a single randomized trial or nonrandomized studies, and level C recommendations are based on the consensus opinion of experts.

INDICATIONS FOR PERMANENT PACING

Acquired Atrioventricular Block

For patients with complete or second-degree atrioventricular (AV) block, the ACC/AHA guidelines consider permanent pacing to be appropriate when the abnormality causes symptoms and is not precipitated by a drug whose use can be discontinued (**Table 36G-1**) or a condition that is likely to be reversible, such as acute inferior myocardial infarction with a narrow QRS complex. Examples of symptoms include fatigue, syncope or presyncope, seizures, congestive heart failure, and confusional states. In asymptomatic patients, pacing is indicated for those at high risk for the development of complications, such as patients with periods of asystole of 3 seconds or longer or an escape rate of less than 40 beats/min or those who have specific high-risk conditions.

The guidelines do not support pacing for patients with asymptomatic first-degree or type I second-degree AV block, and they do not support the use of pacing for patients with hypoxia and sleep apnea syndrome in the absence of symptoms.

Chronic Bifascicular and Trifascicular Block

Syncope is common in these patients, but the risk for sudden death or progression to complete heart block varies in patient subsets.

TABLE 36G-1 Indications for Pacing in Patients with Atrioventricular Block

Class I

1. Third-degree or advanced second-degree AV block at any anatomic level associated with any one of the following conditions:
 - a. Symptoms (including heart failure) or ventricular arrhythmias attributable to AV block. (*Level of evidence: C.*)
 - b. Arrhythmias and other medical conditions requiring drugs that result in symptomatic bradycardia. (*Level of evidence: C.*)
 - c. Documented periods of asystole >3.0 sec, any escape rate <40 beats/min, or any escape rhythm below the AV junction in awake, asymptomatic patients in sinus rhythm. (*Level of evidence: C.*)
 - d. A documented period of asystole >5 sec in awake, asymptomatic patients in atrial fibrillation. (*Level of evidence: C.*)
 - e. After catheter ablation of the AV junction. (*Level of evidence: C.*)
 - f. Postoperative AV block that is not expected to resolve after cardiac surgery. (*Level of evidence: C.*)
 - g. Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb (limb-girdle) muscular dystrophy, and peroneal muscular atrophy, with or without symptoms of bradycardia. (*Level of evidence: B.*)
2. Symptomatic second-degree AV block regardless of type or site of block. (*Level of evidence: B.*)
3. Asymptomatic third-degree AV block at any anatomic site with an average awake ventricular rate >40 beats/min in patients with cardiomegaly or left ventricular dysfunction or if the site of block is below the AV node. (*Level of evidence: B.*)
4. Second- or third-degree AV block during exercise in the absence of myocardial ischemia. (*Level of evidence: C.*)

Class IIa

1. Persistent third-degree AV block at any anatomic site with an average ventricular rate >40 beats/min in asymptomatic adult patients in the absence of cardiomegaly. (*Level of evidence: C.*)
2. Asymptomatic second-degree AV block at the intra- or infra-His levels found at electrophysiologic study. (*Level of evidence: B.*)
3. First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise. (*Level of evidence: B.*)
4. Asymptomatic type II second-degree AV block with a narrow QRS complex. When type II second-degree AV block occurs with a wide QRS complex, including isolated right bundle branch block, pacing becomes a class I recommendation. (*Level of evidence: B.*)

Class IIb

1. Neuromuscular diseases such as myotonic muscular dystrophy, Erb (limb-girdle) dystrophy, and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms of bradycardia. (*Level of evidence: B.*)
2. AV block as a result of drug use or toxicity when the block is expected to recur even after cessation of use of the drug. (*Level of evidence: B.*)

Class III

1. Asymptomatic first-degree AV block. (*Level of evidence: B.*)
2. Asymptomatic type I second-degree AV block at the supra-His (AV node) level or another site or not known to be intra- or infra-Hisian by electrophysiologic study. (*Level of evidence: C.*)
3. AV block expected to resolve and unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone or during hypoxia in sleep apnea in the absence of symptoms). (*Level of evidence: B.*)

TABLE 36G-2 Indications for Pacing in Patients with Chronic Bifascicular and Trifascicular Block

Class I
1. Advanced second-degree AV block or intermittent third-degree AV block. <i>(Level of evidence: B.)</i>
2. Type II second-degree AV block. <i>(Level of evidence: B.)</i>
3. Alternating bundle branch block. <i>(Level of evidence: C.)</i>
Class IIa
1. Syncope not demonstrated to be due to AV block when other probable causes, specifically ventricular tachycardia, have been excluded. <i>(Level of evidence: B.)</i>
2. Incidental finding at electrophysiologic study of a markedly prolonged H-V interval (≥ 100 msec) in asymptomatic patients. <i>(Level of evidence: B.)</i>
3. Incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic. <i>(Level of evidence: B.)</i>
Class IIb
1. Neuromuscular diseases such as myotonic muscular dystrophy, Erb (limb-girdle) dystrophy, and peroneal muscular atrophy with bifascicular block or any degree of fascicular block, with or without symptoms of bradycardia. <i>(Level of evidence: C.)</i>
Class III
1. Fascicular block without AV block or symptoms. <i>(Level of evidence: B.)</i>
2. Fascicular block with first-degree AV block without symptoms. <i>(Level of evidence: B.)</i>

Guidelines for pacing in these settings (Table 36G-2) include alternating bundle branch block as a class I indication because it indicates abnormal and unstable conduction in all three fascicles. The guidelines also support pacing in patients with markedly abnormal infranodal conduction at electrophysiologic studies, even if they are asymptomatic (class IIa). Pacing is not supported for patients without symptoms even if first-degree AV block is also present.

Acute Myocardial Infarction

Symptoms do not play a role in appropriateness for pacing in patients with acute myocardial infarction because of the high risk for sudden death in some postinfarction patients with conduction system disturbances (Table 36G-3). The guidelines emphasize that the requirement for temporary pacing after acute myocardial infarction does not automatically indicate a need for permanent pacing. However, permanent pacemakers are supported in patients with transient (presumed) infranodal AV block and associated bundle branch block, one of the rare times that transient AV block is judged to be an indication for permanent pacing. The usefulness of permanent pacemakers for patients with advanced AV block at the AV node level is less clear (class IIb).

Sinus Node Dysfunction

As for patients with acquired AV block, pacing is indicated for those with symptoms caused by bradycardia that is not the result of a drug whose use can be discontinued (Table 36G-4). Pacing is discouraged in asymptomatic patients, even when resting heart rates are lower than 40 beats/min, and in symptomatic patients when symptoms cannot be proved to be caused by bradycardia. A class IIa recommendation supports pacing in patients with syncope of unexplained origin when major abnormalities in sinus node function are demonstrated at electrophysiologic testing.

Prevention and Termination of Tachyarrhythmias

In some patients with long-QT syndrome, continuous pacing can prevent recurrent tachyarrhythmias. In addition, paroxysmal

TABLE 36G-3 Indications for Permanent Pacing after Acute Myocardial Infarction

Class I
1. Permanent ventricular pacing is indicated for <ol style="list-style-type: none"> Persistent second-degree AV block in the His-Purkinje system with alternating bundle branch block or third-degree AV block within or below the His-Purkinje system after ST-segment elevation myocardial infarction. <i>(Level of evidence: B.)</i> Transient second- or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary. <i>(Level of evidence: B.)</i> Persistent and symptomatic second- or third-degree AV block. <i>(Level of evidence: C.)</i>
Class IIb
1. Permanent ventricular pacing may be considered for persistent second- or third-degree transient AV block at the AV node level, with or without symptoms. <i>(Level of evidence: B.)</i>
Class III
1. Transient AV block without intraventricular conduction defects. <i>(Level of evidence: B.)</i>
2. Transient AV block with isolated left anterior fascicular block. <i>(Level of evidence: B.)</i>
3. Acquired new bundle branch block or fascicular block without AV block. <i>(Level of evidence: B.)</i>
4. Asymptomatic first-degree AV block with bundle branch or fascicular block. <i>(Level of evidence: B.)</i>

TABLE 36G-4 Indications for Pacing in Patients with Sinus Node Dysfunction

Class I
1. Symptomatic bradycardia or frequent symptomatic sinus pauses. <i>(Level of evidence: C.)</i>
2. Symptomatic chronotropic incompetence. <i>(Level of evidence: C.)</i>
3. Symptomatic bradycardia that results from required drug therapy. <i>(Level of evidence: C.)</i>
Class IIa
1. Sinus node dysfunction occurring with a heart rate < 40 beats/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented. <i>(Level of evidence: C.)</i>
2. Syncope of unexplained origin when clinically significant sinus node dysfunction is discovered or provoked during electrophysiologic testing. <i>(Level of evidence: C.)</i>
Class IIb
1. Minimally symptomatic patients with a chronic heart rate < 40 beats/min while awake. <i>(Level of evidence: C.)</i>
Class III
1. Sinus node dysfunction in asymptomatic patients. <i>(Level of evidence: C.)</i>
2. Sinus node dysfunction in patients with symptoms that are clearly documented in the absence of bradycardia. <i>(Level of evidence: C.)</i>
3. Sinus node dysfunction with symptomatic bradycardia caused by nonessential drug therapy. <i>(Level of evidence: C.)</i>

reentrant tachyarrhythmias can be terminated in some patients through programmed stimulation and short bursts of rapid pacing. However, the guidelines do not provide support for the routine use of antitachycardia pacemakers without extensive testing before implantation (Table 36G-5), but they continue to consider bradycardia pacing appropriate (class I indication) for patients with sustained pause-dependent ventricular tachycardia (unrelated to a drug whose use can be discontinued), with or without a prolonged QT interval,

TABLE 36G-5 Indications for Pacemakers to Terminate Tachycardia**Class IIa**

1. Symptomatic recurrent supraventricular tachycardia that is reproducibly terminated by pacing in the unlikely event that catheter ablation and/or drugs fail to control the arrhythmia or produce intolerable side effects. (*Level of evidence: C.*)

Class III

1. The presence of accessory pathways with the capacity for rapid anterograde conduction. (*Level of evidence: C.*)

TABLE 36G-6 Indications for Pacemakers to Prevent Tachycardia**Class I**

1. Pause-dependent sustained ventricular tachycardia with or without a prolonged QT interval. (*Level of evidence: C.*)

Class IIa

1. Pacing is reasonable for patients with congenital long-QT syndrome considered to be at high risk. (*Level of evidence: C.*)

Class IIb

1. Prevention of symptomatic, drug-refractory recurrent atrial fibrillation in patients with coexisting sinus node dysfunction. (*Level of evidence: B.*)

Class III

1. Frequent or complex ventricular ectopic activity without sustained ventricular tachycardia in patients without long-QT syndrome. (*Level of evidence: C.*)
2. Torsades de pointes ventricular tachycardia secondary to reversible causes. (*Level of evidence: A.*)

if the efficacy of temporary pacing has been demonstrated ([Table 36G-6](#)). However, some patients have or are at risk for other types of ventricular tachycardia. In these patients an ICD may be more appropriate.

Carotid Sinus Syndrome and Neurocardiogenic Syncope

The only class I indication for permanent pacing is recurrent syncope caused by carotid sinus stimulation in the absence of any drug that depresses the sinus node or AV conduction ([Table 36G-7](#)). Pacing is discouraged in patients without symptoms or in those who have syncope without bradycardia.

Hypertrophic Cardiomyopathy

The guidelines minimize indications for pacing in patients with hypertrophic cardiomyopathy unless they have associated sinus node dysfunction or AV block that would fulfill related indications for pacing ([Table 36G-8](#)). A class IIb indication permits pacing in medically refractory symptomatic patients with hypertrophic cardiomyopathy and a significant resting or provoked left ventricular (LV) outflow tract gradient. Pacing should really be considered only if the patient is truly refractory to pharmacologic therapy.

Cardiac Transplantation

[Table 36G-9](#) details these indications.

Cardiac Resynchronization Therapy

For guidelines on CRT, [see Chapter 26](#).

TABLE 36G-7 Indications for Pacing in Patients with Neurally Mediated Reflex Syncope**Class I**

1. Recurrent syncope caused by carotid sinus hypersensitivity, defined as minimal carotid sinus pressure inducing ventricular asystole of >3 sec in patients not receiving medications that depress the sinus node or AV conduction. (*Level of evidence: C.*)

Class IIa

1. Syncope in the absence of a definite provocative event with a pause of ≥3 sec with carotid massage. (*Level of evidence: C.*)

Class IIb

1. Recurrent symptomatic neurocardiogenic syncope with a cardioinhibitory response during tilt-table testing. (*Level of evidence: B.*)

Class III

1. A cardioinhibitory response during carotid sinus stimulation without symptoms or with vague symptoms. (*Level of evidence: C.*)
2. Situational vasovagal syncope in which avoidance behavior is effective. (*Level of evidence: C.*)

TABLE 36G-8 Pacing in Patients with Hypertrophic Cardiomyopathy**Class IIb**

1. Medically refractory symptomatic patients with significant resting or provoked LV outflow tract obstruction. (*Level of evidence: A.*)

Class III

1. Asymptomatic patients or those whose symptoms are medically controlled. (*Level of evidence: C.*)
2. Symptomatic patients without LV outflow tract obstruction. (*Level of evidence: C.*)

TABLE 36G-9 Indications for Pacing after Cardiac Transplantation**Class I**

1. Persistent symptomatic or inappropriate bradycardia that is not expected to resolve. (*Level of evidence: C.*)

Class IIb

1. Relative bradycardia is recurrent or prolonged and is limiting rehabilitation or hospital discharge. (*Level of evidence: C.*)
2. Syncope after transplantation without a documented bradyarrhythmia. (*Level of evidence: C.*)

Selection of Pacemakers

The guidelines provide recommendations and decision trees to help physicians match patients' needs to the technology implanted and to anticipate future needs of the patient. In keeping with the guidelines, elderly patients should receive devices according to the same indications as for younger patients ([Table 36G-10](#)).

IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR THERAPY

The 2008 guidelines group all indications together; that is, they no longer separate primary and secondary indications ([Table 36G-11](#)).

**TABLE 36G-10 Indications for Permanent Pacemaker in Children, Adolescents, and Patients with Congenital Heart Disease****Class I**

1. Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output. (*Level of evidence: C.*)
2. Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate. (*Level of evidence: B.*)
3. Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery. (*Level of evidence: B.*)
4. Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction. (*Level of evidence: B.*)
5. Congenital third-degree AV block in an infant with a ventricular rate <55 beats/min or with congenital heart disease and a ventricular rate <70 beats/min. (*Level of evidence: C.*)

Class IIa

1. Congenital heart disease and sinus bradycardia for prevention of recurrent episodes of intra-atrial reentrant tachycardia; sinus node dysfunction may be intrinsic or secondary to antiarrhythmic treatment. (*Level of evidence: C.*)
2. Congenital third-degree AV block beyond the first year of life with an average heart rate <50 beats/min and abrupt pauses in ventricular rate that are 2 or 3 times the basic cycle length or associated with symptoms as a result of chronotropic incompetence. (*Level of evidence: B.*)
3. Sinus bradycardia with complex congenital heart disease and a resting heart rate <40 beats/min or pauses in ventricular rate >3 sec. (*Level of evidence: C.*)
4. Congenital heart disease and impaired hemodynamics as a result of sinus bradycardia or loss of AV synchrony. (*Level of evidence: C.*)
5. Unexplained syncope in a patient with previous congenital heart surgery complicated by transient complete heart block and a residual fascicular block after a careful evaluation to exclude other causes of syncope. (*Level of evidence: B.*)

Class IIb

1. Transient postoperative third-degree AV block that reverts to sinus rhythm with a residual bifascicular block. (*Level of evidence: C.*)
2. Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function. (*Level of evidence: B.*)
3. Asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate <40 beats/min or pauses in ventricular rate >3 sec. (*Level of evidence: C.*)

Class III

1. Transient postoperative AV block with return of normal AV conduction in an otherwise asymptomatic patient. (*Level of evidence: B.*)
2. Asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of previous transient complete AV block. (*Level of evidence: C.*)
3. Asymptomatic type I second-degree AV block. (*Level of evidence: C.*)
4. Asymptomatic sinus bradycardia with the longest relative risk interval <3 sec and a minimum heart rate >40 beats/min. (*Level of evidence: C.*)

TABLE 36G-11 Indications for Implantable Cardioverter-Defibrillator Therapy**Class I**

1. Survivors of cardiac arrest secondary to ventricular fibrillation (VF) or hemodynamically unstable sustained ventricular tachycardia (VT) after evaluation to define the cause of the event and to exclude any completely reversible causes. (*Level of evidence: A.*)
2. Structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable. (*Level of evidence: B.*)
3. Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study. (*Level of evidence: B.*)
4. LV ejection fraction (LVEF) <35% because of previous myocardial infarction in patients at least 40 days after myocardial infarction and in New York Heart Association (NYHA) functional class II or III. (*Level of evidence: A.*)
5. Nonischemic dilated cardiomyopathy in patients who have an LVEF ≤35% and are in NYHA functional class II or III. (*Level of evidence: B.*)
6. LV dysfunction because of previous myocardial infarction in patients who are at least 40 days after myocardial infarction, have an LVEF <30%, and are in NYHA functional class I. (*Level of evidence: A.*)
7. Nonsustained VT because of previous myocardial infarction, LVEF <40%, and inducible VF or sustained VT at electrophysiologic study. (*Level of evidence: B.*)

Class IIa

1. Unexplained syncope, significant LV dysfunction, and nonischemic dilated cardiomyopathy. (*Level of evidence: C.*)
2. Sustained VT and normal or near-normal ventricular function. (*Level of evidence: C.*)
3. Patients with hypertrophic cardiomyopathy and (a) a family history of sudden death presumably caused by hypertrophic cardiomyopathy in 1 or more first-degree relatives, (b) LV wall thickness ≥30 mm, (c) one or more unexplained syncopal episodes in the last 6 months. (*Level of evidence: C.*)
4. Selected patients with hypertrophic cardiomyopathy and either nonsustained VT (particularly those <30 years of age) or an abnormal blood pressure response with exercise* in the presence of other established risk markers[†] or potential risk modifiers.[‡] (*Level of evidence: C.*)
5. Arrhythmogenic right ventricular dysplasia/cardiomyopathy in patients who have 1 or more risk factors for sudden cardiac death. (*Level of evidence: C.*)
6. Long-QT syndrome in patients who are experiencing syncope and/or VT while receiving beta blockers. (*Level of evidence: B.*)
7. Nonhospitalized patients awaiting transplantation. (*Level of evidence: C.*)
8. Brugada syndrome in patients who have had syncope or documented VT that has not resulted in cardiac arrest. (*Level of evidence: C.*)
9. Catecholaminergic polymorphic VT in patients who have syncope and/or documented sustained VT while receiving beta blockers. (*Level of evidence: C.*)
10. Cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. (*Level of evidence: C.*)

TABLE 36G-11 Indications for Implantable Cardioverter-Defibrillator Therapy—cont'd**Class IIb**

1. Nonischemic heart disease in patients with an LVEF $\leq 35\%$ and in NYHA functional class I. (*Level of evidence: C.*)
2. Long-QT syndrome and risk factors for sudden cardiac death. (*Level of evidence: B.*)
3. Syncope and advanced structural heart disease in patients in whom thorough invasive and noninvasive investigations have failed to define a cause. (*Level of evidence: C.*)
4. Familial cardiomyopathy associated with sudden death. (*Level of evidence: C.*)
5. LV noncompaction. (*Level of evidence: C.*)
6. Patients with hypertrophic cardiomyopathy and either an abnormal blood pressure response to exercise* or isolated bursts of nonsustained VT in the absence of any other risk factors† or risk modifiers‡ for sudden cardiac death. (*Level of evidence: C.*)

Class III

1. Patients who do not have a reasonable expectation of survival with acceptable functional status for at least 1 year, even if they meet the ICD implantation criteria specified in the class I, IIa, and IIb recommendations. (*Level of evidence: C.*)
2. Incessant VT or VF. (*Level of evidence: C.*)
3. Significant psychiatric illnesses that may be aggravated by device implantation or may preclude systematic follow-up. (*Level of evidence: C.*)
4. Drug-refractory congestive heart failure in patients who are not candidates for cardiac transplantation or CRT-D. (*Level of evidence: C.*)
5. Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. (*Level of evidence: C.*)
6. When VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with Wolff-Parkinson-White syndrome, right ventricular or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). (*Level of evidence: C.*)
7. Ventricular tachyarrhythmias caused by a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). (*Level of evidence: B.*)

*Defined either as failure to increase by 20 mm Hg or greater or as a drop of 20 mm Hg or greater.

†Established risk markers: Sudden death presumably caused by hypertrophic cardiomyopathy in one or more first-degree relatives, LV wall thickness 30 mm or greater, one or more unexplained syncope episodes in the last 6 months, nonsustained VT, abnormal blood pressure response to exercise.

‡Potential risk modifiers: Resting LV outflow tract gradient 30 mm Hg or greater, late gadolinium enhancement on cardiac magnetic resonance imaging, LV apical aneurysm.

CRT-D = cardiac resynchronization therapy defibrillator.

The strongest evidence for use of ICDs for “secondary prevention” is in patients with LV dysfunction who have been resuscitated from ventricular fibrillation, hemodynamically unstable ventricular tachycardia, or ventricular tachycardia with syncope and who remain at risk for future cardiac arrests. There is also strong evidence supporting the use of ICDs for “primary prevention” in patients at least 40 days after myocardial infarction who have depressed LV function with ejection fractions of less than 30% to 40% and in patients with nonischemic dilated cardiomyopathy who have an ejection fraction of less than 30% to 35%.

However, it is important to recognize the conceptual difference between class I indications for pacing ICDs and those for ICDs for primary prevention. Many class I indications for pacing relieve serious symptoms that occur frequently in day-to-day life. In contrast, class I ICD indications for primary prevention address the risk for infrequent

but catastrophic events, and the decision to implant an ICD should include consideration of the presence of severe comorbid conditions, which could limit benefit from the ICD. In contrast, pacing is almost never withheld from patients with persistent symptomatic bradycardia because of comorbid conditions.

NORMAL SINUS RHYTHM

Normal sinus rhythm is arbitrarily limited to impulse formation beginning in the sinus node at rates between 60 and 100 beats/minute. Infants and children generally have faster heart rates than adults do, both at rest and during exercise. The P wave is upright in electrocardiographic leads I, II, and aVF and negative in lead aVR, with a vector in the frontal plane of between 0 and +90 degrees. In the horizontal plane, the P vector is directed anteriorly and slightly leftward and can therefore be negative in leads V₁ and V₂ but positive in V₃ to V₆. The PR interval exceeds 120 milliseconds (msec) and can vary slightly with the rate. If the pacemaker site (site of impulse origin) shifts, a change in morphology of the P wave can occur. The rate of sinus rhythm varies significantly and depends on many factors, including age, sex, and physical activity.

The sinus nodal discharge rate responds readily to autonomic stimuli. Steady vagal (parasympathetic) stimulation decreases the spontaneous sinus nodal discharge rate and predominates over steady sympathetic stimulation, which increases the spontaneous sinus nodal discharge rate.

Rates lower than 60 beats/minute are considered to be bradycardia, and rates higher than 100 beats/minute are considered to be tachycardia. As described in **Chapter 33**, the normal sequence of electrical activation of the heart is from the sinus node through the atria to the atrioventricular (AV) node and His-Purkinje system and to the ventricular myocardium. Arrhythmias resulting in bradycardia or tachycardia can be thought of as specific disorders of each of these components. Specific tachyarrhythmias and bradyarrhythmias presented as disorders of this electrophysiologic (EP) hierarchy and their characteristics are summarized in **Table 37-1**.

TACHYARRHYTHMIAS

Tachyarrhythmias are broadly characterized as supraventricular tachycardia (SVT), defined as a tachycardia in which the driving circuit or focus originates, at least in part, in tissue above the level of the ventricle (i.e., sinus node, atria, AV node, or His bundle), and ventricular tachycardia (VT), defined as a tachycardia in which the driving circuit or focus originates solely in ventricular tissue or Purkinje fibers. Because of differences in prognosis and management,

distinction between SVT and VT is critical early in the acute management of a tachyarrhythmia.¹ In general (with the exception of idiopathic VT, described later), VT often carries a much graver prognosis, usually implies the presence of significant heart disease, results in more profound hemodynamic compromise, and therefore requires immediate attention and measures to revert to sinus rhythm. SVT is not usually lethal and often does not result in hemodynamic collapse; therefore, more conservative measures can be applied initially to convert to sinus rhythm.^{2,3}

Distinction between SVT and VT can generally be made on the basis of the electrocardiogram (ECG) obtained during tachycardia (**see Chapter 34**).⁴ It is important to obtain a 12-lead ECG during tachycardia if possible and to obtain 12-lead (or at least multilead) rhythm strips during any intervention aimed at termination of the tachycardia because examining the termination (and initiation) can help identify the specific arrhythmia.⁵ In general, if the QRS is narrow (duration <120 msec, often referred to as narrow-complex tachycardias), the ventricle is being activated via the normal His-Purkinje system, and thus the origin of the tachycardia is supraventricular (**Fig. 37-1**). In contrast, a wide QRS (duration >120 msec) during tachycardia suggests VT; however, in some common scenarios SVT can produce a wide QRS complex. Therefore a more descriptive term, *wide-complex tachycardia (WCT)*, is often used when the precise arrhythmia mechanism cannot be determined. For example, SVT with a concurrent bundle branch block or intraventricular conduction defect can produce WCTs despite a supraventricular origin. In addition, preexcited tachycardias (tachycardias in which the ventricle is activated in whole or in part over an accessory pathway) produce wide QRS complexes despite being supraventricular in origin. Therefore, although a narrow-complex tachycardia almost always makes the diagnosis of SVT, a WCT can be supraventricular or ventricular. Fusion or capture beats and AV dissociation are diagnostic of VT (discussed later, **see Ventricular Tachycardia, Electrocardiographic Recognition**) but are often not present or are difficult to detect. Criteria and algorithms have been developed to determine whether a WCT is more likely to be SVT or VT (**see Differentiation between Ventricular and Supraventricular Tachycardia** below).⁴ The general principles behind these algorithms rest on the assumption that the closer the QRS morphology is to a typical bundle branch block pattern, the more likely that it is an SVT and assumes that the septum is still rapidly activated in a WCT because of SVT.

TABLE 37-1 Characteristics of Arrhythmias*

TYPE OF ARRHYTHMIA	P WAVES		QRS COMPLEXES			VENTRICULAR RESPONSE TO CAROTID SINUS MESSAGE	PHYSICAL EXAMINATION			TREATMENT
	Rate (Beats/min)	Rhythm	Contour	Rate (Beats/min)	Rhythm	Contour	Intensity of S ₁	Splitting of S ₂	A Waves	
Sinus rhythm	60-100	Regular ^f	Normal	60-100	Regular	Normal	Gradual slowing and return to former rate	Normal	Normal	None
Sinus bradycardia	<60	Regular	Normal	<60	Regular	Normal	Gradual slowing and return to former rate	Normal	Normal	None, unless symptomatic; atropine
Sinus tachycardia	100-180	Regular	May be peaked	100-180	Regular	Normal	Gradual slowing ^g and return to former rate	Normal	Normal	None, unless symptomatic; treat underlying disease
AV nodal reentry	150-250	Very regular except at onset and termination	Retrograde; difficult to see; lost in QRS complex	150-250	Very regular except at onset and termination	Normal	Abrupt slowing caused by termination of tachycardia or no effect	Normal	Constant cannon a waves	Vagal stimulation, adenosine, verapamil, digitalis, propranolol, DC shock, pacing
Atrial flutter	250-350	Regular	Sawtooth	75-175	Generally regular in absence of drugs or disease	Normal	Abrupt slowing and return to former rate; flutter remains	Normal	Flutter waves	DC shock, digitalis, quinidine, propranolol, verapamil, adenosine
Atrial fibrillation	400-600	Grossly irregular	Baseline undulation, no P waves	100-160	Grossly irregular	Normal	Slowing; gross irregularity remains	Normal	No a waves	Digitalis, quinidine, DC shock, verapamil, adenosine
Atrial tachycardia with block	150-250	Regular; may be irregular	Abnormal	75-200	Generally regular in absence of drugs or disease	Normal	Abrupt slowing and return to normal rate; tachycardia remains	Normal	More a waves than c-v waves	Stop digitalis if toxic; digitalis if not toxic; possibly verapamil
AV junctional rhythm	40-100 ^h	Regular	Normal	40-60	Fairly regular	Normal	None; may be slight slowing	Normal	Intermittent cannon waves	None, unless symptomatic; atropine
Reciprocating tachycardias using an accessory (WPW) pathway	150-250	Very regular except at onset and termination	Retrograde; difficult to see; monitor the QRS complex	150-250	Very regular except at onset and termination	Normal	Abrupt slowing caused by termination of tachycardia or no effect	Normal	Constant cannon waves	See AV nodal reentry earlier
Nonparoxysmal AV junctional tachycardia	60-100 ⁱ	Regular	Normal	70-130	Fairly regular	Normal	None; may be slight slowing	Normal	Intermittent cannon waves ^j	None, unless symptomatic; stop digitalis if toxic

*In an effort to summarize these arrhythmias in tabular form, generalizations have to be made. For example, the response to carotid sinus massage may be slightly different from what is listed. Acute therapy to terminate a tachycardia may be different from chronic therapy to prevent recurrence. Some of the exceptions are indicated in the footnotes; the reader is referred to text for a complete discussion.

[†]P waves initiated by sinus node discharge may not be precisely regular because of sinus arrhythmia.

[‡]Frequently, carotid sinus massage fails to slow a sinus tachycardia.

[§]Any independent atrial arrhythmia may exit or the atria may be captured retrogradely.

^{||}Constant if the atria are captured retrogradely.

[¶]Atrial rhythm and rate may vary, depending on whether sinus bradycardia, sinus tachycardia, or another abnormality is the atrial mechanism.

^{**}Regular or constant if block is unchanging.

SUPRAVENTRICULAR RHYTHM DISTURBANCES

Sinus Tachycardia

Electrocardiographic Recognition

During sinus tachycardia (Fig. 37-2), the sinus node exhibits a discharge frequency between 100 and 180 beats/minute, but it can be higher with extreme exertion and in young individuals. The maximum heart rate achieved during strenuous physical activity varies widely but decreases with age. Sinus tachycardia generally has a gradual onset and termination. The P-P interval can vary slightly from cycle to cycle, especially at slower rates. P waves have a normal contour, a larger amplitude can develop, and the wave can become peaked. They appear before each QRS complex with a stable PR interval unless concomitant AV block ensues.

FIGURE 37-2 Sinus tachycardia (150 beats/min) in a patient during acute myocardial ischemia; note the ST-segment depression. P waves are indicated by arrowheads.

Accelerated phase 4 diastolic depolarization of sinus nodal cells (see Chapter 33) is generally responsible for sinus tachycardia and is usually caused by elevated adrenergic tone or withdrawal of parasympathetic tone. Carotid sinus massage and Valsalva or other vagal maneuvers gradually slow sinus tachycardia, which then accelerates to its previous rate on cessation of the enhanced vagal tone. More rapid sinus rates can fail to slow in response to a vagal maneuver, particularly those driven by high adrenergic tone.

Clinical Features

Sinus tachycardia is common in infancy and early childhood and is the normal reaction to various physiologic or pathophysiologic stress, such as fever, hypotension, thyrotoxicosis, anemia, anxiety, exertion, hypovolemia, pulmonary emboli, myocardial ischemia, congestive heart failure, and shock. Drugs such as atropine, catecholamines, and thyroid medications, as well as alcohol, nicotine, caffeine, and amphetamines or other stimulants, can produce sinus tachycardia. Persistent sinus tachycardia can be a manifestation of heart failure.

In patients with structural heart disease, sinus tachycardia can result in reduced cardiac output or angina or can precipitate another arrhythmia, in part related to the abbreviated ventricular filling time and compromised coronary blood flow. Sinus tachycardia can be a cause of inappropriate defibrillator discharge in patients with an implantable cardioverter-defibrillator (ICD; see Chapter 36). Chronic inappropriate sinus tachycardia (also known as the syndrome of inappropriate sinus tachycardia) has been described in otherwise healthy persons, possibly secondary to increased automaticity of the sinus node or an automatic atrial focus near the sinus node.⁶ The abnormality can result from a defect in either sympathetic or vagal nerve control of sinoatrial (SA) automaticity or from an abnormality of the intrinsic heart rate. In postural orthostatic tachycardia syndrome, a related syndrome consisting of orthostatic hypotension and sinus tachycardia, the cause of the orthostatic decrease in blood pressure is not hypovolemia or drugs. Both syndromes can result from autonomic neuropathy (either peripheral, as in diabetic patients, or central, from spinal cord injury).

Sinus node reentry (Fig. e37-1) is an atrial tachycardia originating from tissue near the sinus node and thus has a P wave morphology similar to sinus rhythm (see the section **Focal Atrial Tachycardias**).

Management

Management should focus on the cause of the sinus tachycardia. In the hospital inpatient setting, the cause is usually obvious (e.g., hemorrhage, sepsis, agitation), whereas in the outpatient setting, it may be more elusive. The most common reversible causes include hyperthyroidism, anemia, infection or inflammation, and hypovolemia. Diabetic neuropathy is also common but not reversible. Elimination of tobacco, alcohol, caffeine, or other stimulants, such as the sympathomimetic agents in nose drops and cold medications, may be helpful. Beta blockers and nondihydropyridine calcium channel blockers (verapamil and diltiazem), fluid replacement in a hypovolemic patient, or fever reduction in a febrile patient can help slow the sinus nodal discharge rate. Treatment of inappropriate sinus tachycardia requires beta blockers or calcium channel blockers, alone or in combination. In severe cases, sinus node radiofrequency (RF) or surgical ablation may be indicated; however, these approaches are usually only temporarily palliative (see Chapter 35). A specific blocker

FIGURE e37-1 Sinus node reentry. After three spontaneous sinus-initiated beats, premature stimulation of the high right atrium (S₂, S₃) initiates a sustained tachycardia at a cycle length of 450 milliseconds that has the identical high-low atrial activation sequence characteristic of sinus node discharge. This is sinus node reentry. Leads I, II, III, and V₁ are scalar leads. H = His electrogram; HBE = His bundle electrogram; HRA = high right atrial electrogram; RV = right ventricular electrogram. Numbers are milliseconds.

of the pacemaker current (I_f), ivabradine, has been useful in some patients with inappropriate or refractory sinus tachycardia.

Premature Atrial Complexes

Premature complexes are among the most common causes of an irregular pulse and palpitations. They can originate from any area in the heart—most frequently from the ventricles, less often from the atria and the AV junctional area, and rarely from the sinus node. Premature complexes are common in normal hearts and increase in frequency with age.

Electrocardiographic Recognition

The diagnosis of premature atrial complexes (PACs) is made on the ECG (Fig. 37-3) by the presence of a premature P wave with a PR interval exceeding 120 milliseconds (except in Wolff-Parkinson-White [WPW] syndrome, in which case the PR interval is generally shorter than 120 msec). Although the contour of a premature P wave can resemble that of a normal sinus P wave, it generally differs. Even though variations in the basic sinus rate can at times make the

diagnosis of prematurity difficult, differences in the contour of the P waves are usually apparent and indicate a different focus of origin. When a PAC occurs early in diastole, conduction may not be completely normal. The AV junction may still be refractory from the preceding beat and prevent propagation of the impulse (blocked or nonconducted PAC; Fig. 37-3A) or cause conduction to be slowed (PAC with a prolonged PR interval). As a general rule, the RP interval is inversely related to the PR interval; thus, a short RP interval produced by an early PAC occurring close to the preceding QRS complex is followed by a long PR interval. When PACs occur early in the cardiac cycle, the premature P waves can be difficult to discern because they are superimposed on T waves. Careful examination of tracings from several leads may be necessary before the PAC is recognized as a slight deformity of the T wave. Frequently, such PACs are blocked before reaching the ventricle and can be misinterpreted as a sinus pause or sinus exit block (see Fig. 37-3A).

The length of the pause that follows any premature complex or series of premature complexes is determined by the interaction of several factors. If the PAC occurs when the sinus node and perinodal tissue are not refractory, the impulse can be conducted into the sinus node,

discharge it prematurely, and cause the next sinus cycle to begin from that time. The interval between the two normal P waves flanking a PAC that has reset the timing of the basic sinus rhythm is less than twice the normal P-P interval, and the pause after the PAC is said to be noncompensatory (Fig. 37-3E, F). Reset (noncompensatory pause) occurs when the A_1 - A_2 interval plus the A_2 - A_3 interval is less than two times the A_1 - A_1 interval and the A_2 - A_3 interval is greater than the A_1 - A_1 interval. The interval between the PAC (A_2) and the following sinus-initiated P wave (A_3) exceeds one sinus cycle but is less than fully compensatory (see later) because the A_2 - A_3 interval is lengthened by the time that it takes the ectopic atrial impulse to be conducted to the sinus node and depolarize it and then for the sinus impulse to return to the atrium. These factors lengthen the return cycle, that is, the interval between the PAC (A_2) and the following sinus-initiated P wave (A_3) (see Fig. 37-3E, F). Premature discharge of the sinus node by an early PAC can temporarily depress sinus nodal automatic activity and cause the sinus node to beat more slowly initially (Fig. 37-3D). Often when this happens, the interval between the A_3 and the next sinus-initiated P wave exceeds the A_1 - A_1 interval.

Less commonly, the PAC encounters a refractory sinus node or perinodal tissue (see Fig. 37-3F), in which case the timing of the basic sinus rhythm is not altered because the sinus node is not reset by the PAC and the interval between the two normal sinus-initiated P waves flanking the PAC is twice the normal P-P interval. The interval that follows this premature atrial discharge is said to be a full compensatory pause, that is, of sufficient duration that the P-P interval bounding the PAC is twice the normal P-P interval. However, sinus arrhythmia can lengthen or shorten this pause. Rarely, an interpolated PAC may occur. In this

FIGURE 37-3 A, PACs that block conduction entirely or conduct with a functional right or functional left bundle branch block. Depending on the preceding cycle length and coupling interval of the PAC, the PAC blocks conduction entirely in the AV node (arrowhead \uparrow) or conducts with a functional left bundle branch block (arrowhead \downarrow) or functional right bundle branch block (arrowhead \rightarrow). B, A PAC on the left (arrowhead) initiates AV nodal reentry that is caused by reentry antegradely and retrogradely over two slow AV nodal pathways, with a retrograde P wave produced midway in the cardiac cycle. On the right, a PAC (arrowhead) initiates AV nodal reentry as a result of anterograde conduction over the slow pathway and retrograde conduction over the fast pathway (see Fig. 37-8A), which produces a retrograde P wave in the terminal portion of the QRS complex that simulates an r' wave. C, D, A PAC (arrowhead \downarrow) initiating a short run of atrial flutter (C) and a PAC (arrowhead \uparrow) depressing return of the next sinus nodal discharge (D). A slightly later PAC (arrowhead \downarrow) in D does not depress sinus nodal automaticity. B-D, Monitor leads.

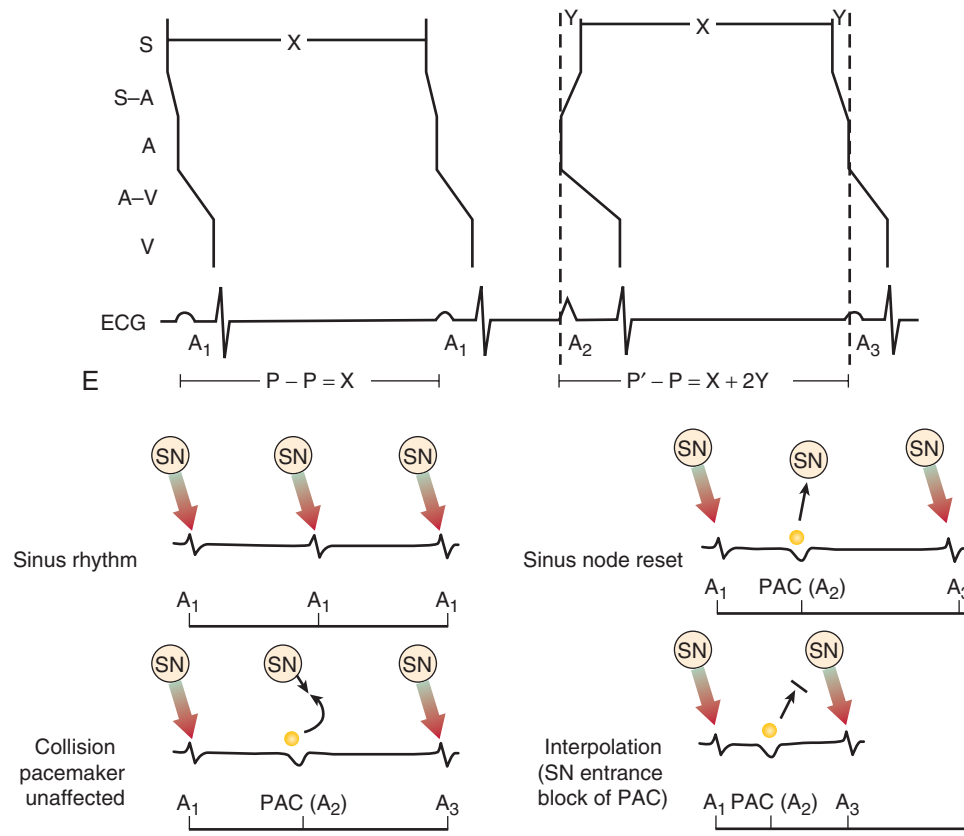

FIGURE 37-3, cont'd E, Diagrammatic example of the effects of a PAC. The sinus interval (A₁-A₁) equals X. The third P wave represents a PAC (A₂) that reaches and discharges the SA node, which causes the next sinus cycle to begin at that time. Therefore the P-P (A₂-A₃) interval equals X + 2Y milliseconds, assuming no depression of SA nodal automaticity. **F**, Diagram of the interactions of a PAC (yellow circles indicate origin; QRS complexes omitted) with the sinus node (SN) depending on the degree of prematurity. The top represents spontaneous sinus rhythm. The bottom is a late coupled PAC that collides with the exiting sinus impulse and therefore does not affect (or reset) the sinus pacemaker. The next sinus impulse (S₂) occurs at exactly twice the sinus interval. An early coupled PAC in the next diagram is able to penetrate the SN and resets the pacemaker, thereby resulting in resetting of the SN (as depicted in **E**). An even earlier coupled PAC in the lower part of the figure reaches refractory tissue around the SN and is thus unable to penetrate it (SN entrance block); therefore, it does not affect SN discharge. The next spontaneous sinus beat (S₂) arrives exactly at the sinus interval. (**E**, Modified from Zipes DP, Fisch C: Premature atrial contraction. *Arch Intern Med* 128:453, 1971.)

case the pause after the PAC is very short, and the interval bounded by the normal sinus-initiated P waves on each side of the PAC is equal to one normal P-P cycle length or slightly longer. The interpolated PAC fails to affect the sinus nodal pacemaker, and the sinus impulse that follows the PAC is conducted to the ventricles, often with a slightly lengthened PR interval. An interpolated atrial or ventricular premature complex of any type represents the only type of premature systole that does not actually replace the normally conducted beat. PACs can originate in the sinus node and are identified by premature P waves that have a contour identical to that of the normal sinus P wave.

On occasion, when the AV node has had sufficient time to repolarize and conduct without delay, the supraventricular QRS complex initiated by the PAC can be aberrant in configuration because the His-Purkinje system or ventricular muscle has not completely repolarized and conducts with a functional delay or block (see Fig. 37-3A). The refractory period of cardiac fibers is directly related to cycle length. (In an adult, the effective AV nodal refractory period is prolonged at shorter cycle lengths.) A slow heart rate (long cycle length) produces a longer His-Purkinje refractory period than does a faster heart rate. As a consequence, a PAC that follows a long R-R interval (long refractory period) can result in a functional bundle branch block (aberrant ventricular conduction). Because the right bundle branch at long cycles has a longer refractory period than the left bundle branch does, aberration with a right bundle branch block pattern at slow rates occurs more commonly than aberration with a left bundle branch block pattern. At shorter cycles, the refractory period of the left bundle branch

exceeds that of the right bundle branch, and a left bundle branch block pattern may be more likely to occur.

Clinical Features

PACs can occur in various situations, such as during infection, inflammation, or myocardial ischemia, or they can be provoked by various medications, tension states, tobacco, alcohol, or caffeine. PACs can precipitate or presage the occurrence of sustained supraventricular (Fig. 37-3B, C) and, rarely, ventricular tachyarrhythmias. Frequently, PACs occur without any reversible causes and increase in frequency with aging. In general, PACs have a benign prognosis. Most patients do not have significant symptoms with PACs; however, those who do have symptoms most often feel the pauses that occur after the PAC.

Management

PACs generally do not require therapy. In symptomatic patients or when the PACs precipitate tachycardias, treatment with a beta blocker or a calcium antagonist can be attempted. In drug-refractory, highly symptomatic cases, ablation of the PAC focus can be effective when a single focus can be identified.

Atrial Fibrillation

See Chapter 38.

Atrial Tachycardias

Three types of atrial tachycardia have been distinguished experimentally—automatic, triggered, and reentrant.

Entrainment, resetting patterns in response to overdrive pacing, the patient's response to adenosine, recording of monophasic action potentials, and the mode of initiation may suggest the presence of one of these mechanisms. However, in most cases no clear identification of the mechanism can be made clinically because the clinical and EP features can overlap, especially when the reentrant circuit is small (i.e., microreentry). For example, adrenergic stimulation can initiate automatic and triggered atrial tachycardias, and burst pacing may initiate triggered and microreentrant atrial tachycardias. Therefore, because it determines the approach to mapping and management, atrial tachycardias are more broadly characterized clinically as being focal (originating from a small area of the atrium with atrial excitation emanating from this focus) or macroreentrant (a relatively large reentrant circuit using conduction barriers to create the circuit).⁷ Atrial flutter is the most common type of macroreentrant atrial tachycardia.

Atrial Flutter and Other Macroreentrant Atrial Tachycardias

Atrial flutter is the prototypic macroreentrant atrial rhythm. The typical atrial flutter is a reentrant rhythm in the right atrium that is constrained anteriorly by the tricuspid annulus and posteriorly by the crista terminalis and eustachian ridge. The flutter can circulate in a counterclockwise direction around the tricuspid annulus in the frontal plane (typical flutter, counterclockwise flutter) or in a clockwise direction (atypical, clockwise, or reverse flutter). Because both

these forms of atrial flutter use the same circuit and are constrained by the same anatomic structures, their rates and flutter wave morphology on the surface ECG are consistent and predictable (see later). Rarely, intra-isthmus flutter can occur when the reentrant circuit is isolated to the cavotricuspid isthmus rather than rotating around the entire tricuspid annulus; this typically occurs after ablation in this region (usually done as treatment of typical flutter). Other forms of atrial flutter are now recognized as distinct types and include atrial macroreentry caused by incisional scars from previous atrial surgery, previous atrial ablation, mitral annular flutter, idiopathic fibrosis in areas of the atrium, or other anatomic or functional barriers to conduction in the atria. Because the barriers that constrain these atrial flutters are variable, the electrocardiographic pattern of these so-called atypical atrial flutters can be varied. Sometimes, flutter wave morphology changes during the same episode of flutter, which indicates multiple circuits or nonfixed conduction barriers.

Electrocardiographic Recognition

The atrial rate during typical atrial flutter is usually 250 to 350 beats/minute, although it is occasionally slower, particularly when the patient is treated with antiarrhythmic drugs, which can reduce the rate to about 200 beats/minute. If such slowing occurs, the ventricles can respond in a 1:1 fashion to the slower atrial rate.

In typical atrial flutter, the ECG reveals identically recurring, regular, sawtooth flutter waves (see Fig. 37-3C) and evidence of continual electrical activity (lack of an isoelectric interval between flutter waves), often best visualized in leads II, III, aVF, or V₁ (Fig. 37-4).⁸ In some cases, transient slowing of the ventricular response, via either carotid sinus massage or adenosine, is necessary to visualize the flutter waves. The flutter waves for the most common form of atrial flutter, counterclockwise typical atrial flutter, are inverted (negative) in these leads because of a counterclockwise reentrant pathway, and sometimes they are upright (positive) when the reentrant loop is clockwise (see Fig. 37-4). When the flutter waves are upright from clockwise rotation, they are often notched. If the AV conduction ratio remains constant, the ventricular rhythm will be regular; if the ratio of conducted beats varies (generally the result of a Wenckebach AV block), the ventricular rhythm will be irregular, although this is rare. Various degrees of penetration into the AV

junction by flutter impulses can also influence AV conduction. The ratio of flutter waves to conducted ventricular complexes is most often an even number (e.g., 2:1, 4:1).

As mentioned earlier, because the circuits for atypical flutter (not involving the cavotricuspid isthmus) can be variable, the electrocardiographic features of these macroreentrant atrial tachycardias are highly variable, without consistent rates or flutter wave contours (see Fig. e37-2). However, these tachycardias frequently have a flutter rate similar to that of typical flutter (250 to 390 beats/min). Table 37-2 shows common electrocardiographic findings with the different types of macroreentrant atrial flutter. After extensive left atrial ablation for atrial fibrillation, the electrocardiographic pattern of even typical flutter can appear “atypical” (not have the typical appearance described before) because of the altered left atrial activation as a result of altered conduction secondary to the left atrial ablation. In addition, unusual forms of atrial flutter can occur around ablation lines.

Clinical Features

Atrial flutter is less common than atrial fibrillation. It can occur as a result of atrial dilation from septal defects, pulmonary emboli, mitral or tricuspid valve stenosis or regurgitation, heart failure, previous extensive atrial ablation, and aging, but it can also occur without underlying heart disease. Toxic and metabolic conditions that affect the heart, such as thyrotoxicosis, alcoholism, and pericarditis, can cause atrial flutter. It can follow surgical repair of congenital heart disease. When it follows reparative surgery for congenital heart disease, most patients will be able to have both typical flutter and atypical flutter involving the atriotomy, which often occurs years after the surgery.

Atrial flutter usually responds to carotid sinus massage with a decrease in the ventricular rate in stepwise multiples and returns in reverse manner to the former ventricular rate at the termination of carotid massage. Physical examination may reveal rapid flutter waves in the jugular venous pulse. If the relationship of flutter waves to conducted QRS complexes remains constant, the first heart sound will have a constant intensity. Sounds caused by atrial contraction can occasionally be auscultated.

Management

Cardioversion (see Chapter 35) is commonly the initial treatment of choice for atrial flutter because it promptly and effectively restores sinus rhythm. Cardioversion can be accomplished with synchronous direct current (DC), which often requires relatively low energy (≈50 J). If the electrical shock results in atrial fibrillation, a second shock at a higher energy level is used to restore sinus rhythm, or depending on clinical circumstances, the atrial fibrillation can be left untreated and can revert to atrial flutter or sinus rhythm. The short-acting antiarrhythmic medication ibutilide can also be given intravenously to convert atrial flutter. Ibutilide appears to successfully cardiovert approximately 60% to 90% of episodes of atrial flutter. However, because this medication prolongs the QT interval, torsades de pointes is a potential complication during and shortly after the infusion. Other medications, such as procainamide or amiodarone, can be given to convert atrial flutter chemically, but they are generally less effective than ibutilide. Rapid atrial pacing with a catheter in the esophagus or the right atrium can effectively terminate typical and some forms of atypical atrial flutter in most

FIGURE 37-4 Twelve-lead ECG showing counterclockwise and clockwise atrial flutter. In counterclockwise atrial flutter, the flutter waves are negative in leads II, III, aVF, and V₆ and upright in V₁. In clockwise atrial flutter, the flutter waves are upright in leads II, III, and aVF and often notched.

FIGURE e37-2 Macroreentrant atrial tachycardia in a patient who underwent repair of an atrial septal defect 10 years earlier. This tachycardia uses a reentrant circuit established by the atriotomy on the lateral atrial wall. Ablation to extend the scar to the tricuspid annulus eliminated this tachycardia.

TABLE 37-2 Characteristics of Different Types of Atrial Flutter and Distinguishing Features on Scalar Electrocardiography

TYPE	REENTRANT CIRCUIT	ECG PATTERN	LEAD V ₁ /V ₆
Typical counterclockwise	Tricuspid annulus dependent on the CTI	Sawtooth flutter wave; negative in II, III, and aVF	Positive V ₁ Negative V ₆
Typical clockwise	Tricuspid annulus dependent on the CTI	"Inverse sawtooth"; positive and often notched in II, III, and aVF	Broad and negative in V ₁ (often notched) Positive in V ₆
Lower loop reentry	CTI	Usually similar to typical counterclockwise CTI flutter except subtle loss of terminal positive deflection in leads II, III, and aVF	Usually similar to typical counterclockwise
Upper loop reentry	SVC and upper crista terminalis	Similar to typical clockwise flutter	Similar to typical clockwise flutter
Right atrial free wall	Around areas of scar in the lateral or posterior right atrium (caused by previous atrial surgery or spontaneously)	Variable	Typically negative or biphasic with terminal negative deflection in V ₁
Septal atrial flutter	Atrial septum, typically after previous surgery	Variable	Usually biphasic or isoelectric in V ₁
Mitral annular flutter	Around the mitral annulus, often slow zone of block around the PV interval; frequently occurs in the setting of left atrial surgery or ablation	Variable; I, III, and aVF, often positive but low amplitude	Usually positive in V ₁ (or rarely isoelectric) and often broad
Post-atrial fibrillation ablation/MAZE flutter	Variable; the circuit involves previous ablations or scar in the left atrium	Variable	Variable

CTI = cavotricuspid isthmus.

patients. Because ablation is highly effective for typical flutter and because of the high relapse rate after cardioversion, ablation is the preferred approach for stable patients who do not require immediate cardioversion. Although the risk for thromboembolism is lower than that for atrial fibrillation, patients with atrial flutter do appear to have a risk for thromboembolism immediately after conversion to sinus rhythm. In general, indications for anticoagulation in patients with atrial flutter are similar to those in patients with atrial fibrillation.

As a general rule, atrial flutter is much more difficult to rate-control than atrial fibrillation is. To slow the ventricular response, verapamil (see Chapter 35), given as an initial bolus of 2.5 to 10 mg intravenously (may repeat with an additional 5 to 10 mg after 15 to 30 minutes), or diltiazem, 0.25 mg/kg, can be tried. Adenosine produces a transient AV block and can be used to reveal flutter waves if diagnosis of the arrhythmias is in doubt; it will not generally terminate the atrial flutter and can provoke atrial fibrillation. Esmolol, a beta-adrenergic blocker with a 9-minute elimination half-life, or other intravenous beta blockers can be used to slow the ventricular rate. If the use of calcium channel blockers and beta blockers in combination is insufficient, digoxin can be added. The dose of digitalis necessary to slow the ventricular response varies and at times can result in toxic levels because it is often difficult to slow the ventricular rate during atrial flutter. Intravenous administration of amiodarone can slow the ventricular rate as effectively as digoxin can.

If the atrial flutter persists or recurs, class IA, IC, or III drugs (see Chapter 35) can be tried in an attempt to restore sinus rhythm and prevent recurrence of the atrial flutter. Side effects of these drugs, especially proarrhythmic responses, must be carefully considered (see Chapter 35). Treatment of the underlying disorder, such as thyrotoxicosis, is sometimes necessary to effect conversion to sinus rhythm. In many cases, atrial flutter can continue (or even become more persistent) while taking antiarrhythmic drugs, and the flutter rate will slow. Class I or III drugs should not be used unless the ventricular rate during atrial flutter has been slowed with a calcium antagonist or beta-blocking drug. Because of the ability of class I drugs to slow the flutter rate, AV conduction can be facilitated sufficiently to result in a 1:1 ventricular response to the atrial flutter (Fig. 37-5).

Prevention of recurrent atrial flutter is frequently difficult to achieve medically but should be approached as outlined for atrial fibrillation

(see Chapters 35 and 38). Catheter ablation should be considered in patients with symptomatic or recurrent atrial flutter. Catheter ablation of typical flutter (counterclockwise and clockwise) is a highly effective cure and has a long-term success rate of 90% to 100%. Because ablation of atrial flutter is so effective and poses little risk, it can be offered as an alternative to drug therapy. Ablation of other forms of macroreentrant atrial tachycardia is also effective, although success rates are somewhat lower and more variable. Increasing evidence has indicated that the risk for emboli in patients with atrial flutter may be more significant than once thought. Consequently and because many patients with atrial flutter also have atrial fibrillation, anticoagulation is usually warranted. However, carefully controlled studies to determine the degree of embolic risk in patients with only atrial flutter are lacking. Long-term anticoagulation, as for atrial fibrillation, should probably be considered until more definitive data are available.

Focal Atrial Tachycardias Electrocardiographic Recognition

Focal atrial tachycardias (Fig. 37-6) generally have atrial rates of 150 to 200 beats/minute, with a P wave contour different from that of the sinus P wave.⁹ However, atrial tachycardias with foci near the sinus node can have P wave contours very similar to those in sinus rhythm. At onset there may be some warming up of the rate that results in a slight increase in the heart rate over the initial several complexes. Frequently, atrial tachycardias occur in short, recurrent bursts with spontaneous terminations. However, more incessant forms of atrial tachycardia do occur. P waves are generally found in the second half of the tachycardia cycle (long RP–short PR tachycardia). If the atrial rate is not excessive and AV conduction is not depressed, each P wave can conduct to the ventricles. If the atrial rate increases and AV conduction becomes impaired, a Wenckebach (Mobitz type I) second-degree AV block can ensue. This aberration is sometimes called atrial tachycardia with block. When it is caused by digitalis, other manifestations of digitalis excess are present, such as premature ventricular complexes (PVCs). In nearly half the cases of atrial tachycardia with block, the atrial rate is irregular. Characteristic isoelectric intervals between P waves, in contrast to atrial flutter, are usually present in all leads. However, at rapid atrial rates, distinction between atrial tachycardia with block and atrial flutter can be

FIGURE 37-5 Atrial flutter with 1:1 conduction and QRS widening caused by flecainide. **A**, Atrial flutter occurs with 1:1 conduction and a widened QRS because of slowing of the atrial flutter rate as a result of flecainide and acceleration of conduction through the AV node, which leads to a rapid ventricular response. This rapid ventricular response results in a widened QRS complex because of the use dependence of sodium channel blocking by flecainide. **B**, After administration of AV nodal-blocking agents (in this case, metoprolol), 2:1 conduction occurs, the ventricular rate is slowed, and the QRS duration shortens. In addition, the flutter waves are now apparent on the ECG (arrows).

difficult. Analysis of P wave configuration during tachycardia indicates that a positive or biphasic P wave in V_1 predicts a left atrial focus whereas a negative P wave in V_1 predicts a right atrial focus.

Clinical Features

Atrial tachycardia occurs commonly in patients with significant structural heart disease such as coronary artery disease, with or without myocardial infarction, heart failure, and cor pulmonale, as well as in patients without structural heart disease. It can also occur with digitalis intoxication, often precipitated by potassium depletion. The signs, symptoms, and prognosis are usually related to the underlying cardiovascular status and the rate of the tachycardia. Atrial tachycardias frequently occur in short recurrent bursts but on occasion can be incessant. When they are incessant, tachycardia-induced cardiomyopathy can result. This may be partially or totally reversible with elimination of the tachycardia. In some patients, exercise or stress can provoke the tachycardia; in others, the tachycardia may be positional. Stimulants such as caffeine, chocolate, and ephedrine can also provoke episodes.

Physical findings during a variable rhythm include variable intensity of the first heart sound and systolic blood pressure as a result of the varying AV block and PR interval. An excessive number of *a* waves can be seen in the jugular venous pulse. Carotid sinus massage or administration of adenosine increases the degree of AV block by slowing the ventricular rate in stepwise fashion without terminating the tachycardia, as in atrial flutter. It should be performed cautiously in patients with digitalis toxicity because serious ventricular arrhythmias can result. On occasion, carotid sinus massage or adenosine can terminate some forms of atrial tachycardia.

Management

Depending on the clinical situation, a beta blocker or a calcium channel blocker can be administered to slow the ventricular rate; if atrial tachycardia is still present, class IA, IC, or III drugs can be added. Catheter ablation procedures are generally effective in eliminating the atrial tachycardia, depending on the mechanism and underlying heart disease.⁷ Ablation should be considered in those who fail drug therapy and can be considered as a first-line alternative in patients without underlying heart disease. The most important factor for successful ablation is the ability to induce the tachycardia during the procedure, usually with programmed stimulation and the use of catecholaminergic agents such as isoproterenol. Inducibility can be variable, depending on the mechanism of the atrial tachycardia. Atrial tachycardias can occasionally recur at a different site after successful ablation. If atrial tachycardia develops in a patient taking digitalis, the drug should initially be assumed to be responsible for the arrhythmia and its use stopped. Administration of digitalis antibodies should be considered in unstable patients.

Chaotic Atrial Tachycardia. Chaotic (sometimes called multifocal) atrial tachycardia is characterized by atrial rates between 100 and 130 beats/minute along with marked variation in P wave morphology and totally irregular P-P intervals (Fig. 37-7). In general, at least three P wave contours are noted, with most P waves being conducted to the ventricles, although often with variable PR intervals. This tachycardia occurs commonly in older patients with chronic obstructive pulmonary disease and congestive heart failure and may eventually develop into atrial fibrillation. Digitalis appears to be an unusual cause, and theophylline administration has been implicated. Chaotic atrial tachycardia can occur in childhood.

Management. Management is directed primarily toward the underlying disease. Antiarrhythmic agents are frequently ineffective in slowing either the rate of the atrial tachycardia or the ventricular response. Beta adrenoceptor blockers should be avoided in patients with bronchospastic pulmonary disease but can be effective if tolerated. Verapamil and amiodarone have been useful. Potassium and magnesium replacement may suppress the tachycardia. Ablation may be effective in some cases.

FIGURE 37-6 Atrial tachycardia. This 12-lead ECG and rhythm strip (bottom) demonstrate atrial tachycardia at a cycle length of approximately 520 milliseconds. Conduction varies between 3:2 and 2:1. Note the negative P waves in leads II, III, and aVF and, when consecutive P waves are conducted, that the RP interval exceeds the PR interval. Note also that the tachycardia persists despite the development of an AV block, an important finding that excludes participation of an AV accessory pathway and sharply differentiates this tachycardia from the one shown in Figure 37-21.

FIGURE 37-7 Chaotic (multifocal) atrial tachycardia. PACs occur at varying cycle lengths and with different contours.

Tachycardias Involving the Atrioventricular Junction

Confusion exists about the nomenclature of tachycardias characterized by a supraventricular QRS complex, a regular R-R interval, and no evidence of ventricular preexcitation. Because various EP mechanisms can account for these tachycardias (Fig. 37-8), the nonspecific term *paroxysmal supraventricular tachycardia* has been proposed to encompass the entire group. This term may be inappropriate, however, because some tachycardias in patients with accessory pathways (see later) are no more supraventricular than they are ventricular in origin since they may require participation of both the atria and the ventricles in the reentrant pathway and exhibit a QRS complex of normal contour and duration only because anterograde conduction occurs over the normal AV node–His bundle pathways (see Fig. 37-8C). If conduction over the reentrant pathway reverses direction and travels in an “antidromic” direction (i.e., to the ventricles over

the accessory pathway and to the atria over the AV node–His bundle), the QRS complex exhibits a prolonged duration, although the tachycardia is basically the same. The term *reciprocating tachycardia* has been offered as a substitute for paroxysmal SVT, but use of such a term presumes the mechanism of the tachycardia to be reentrant, which is probably the case for most but not all SVTs. Thus, no universally acceptable nomenclature exists, but rather descriptive labels for specific arrhythmias, as used throughout this chapter.

Atrioventricular Nodal Reentrant Tachycardia Electrocardiographic Recognition

Reentrant tachycardia involving the AV node is characterized by a tachycardia with a QRS complex of supraventricular origin, sudden onset and termination generally at rates of between 150 and 250 beats/minute (usually 180 to 200 beats/minute in adults), and a regular rhythm.¹⁰ Uncommonly, the rate may be as low as 110 beats/minute; occasionally, especially in children, it may exceed 250 beats/minute. Unless functional aberrant ventricular conduction or a previous conduction defect exists, the QRS complex is normal in contour and duration. P waves are generally buried in the QRS complex. Frequently, the P wave occurs just before or just after the end of the QRS complex and causes a subtle alteration that results in a pseudo-S or pseudo-r', which may be recognized only on comparison with the QRS complex in normal sinus rhythm (Fig. 37-9). When seen, P waves are generally directed superiorly and are relatively narrow. AV nodal reentry begins abruptly, usually after a PAC that conducts with a prolonged PR interval (see Figs. 37-3B and 37-8A). The R-R interval can shorten over the course

of the first few beats at the onset or lengthen during the last few beats preceding termination of the tachycardia. Variation in cycle length, particularly at the onset of tachycardia or just before termination, is usually caused by variation in anterograde AV nodal conduction time. Cycle length or QRS alternans can occur, generally when the rate is very fast. Carotid sinus massage can slow the tachycardia slightly before its termination or, if termination does not occur, can produce only slight slowing of the tachycardia.

Electrophysiologic Features. An atrial complex that conducts with a critical prolongation of AV nodal conduction time generally precipitates AV nodal reentry (Figs. 37-10 and 37-11). Premature ventricular stimulation can also induce AV nodal reentry in about a third of patients. Data from the results of RF catheter ablation and mapping support the presence of differential atrial input into the AV node, the fast and slow pathways, to explain this tachycardia (see Chapters 33 and 35). In Figure 37-8A and B, the atria are shown as a necessary link between the fast and slow pathways. Whether these pathways are discrete pathways (perhaps caused by anisotropy) or are

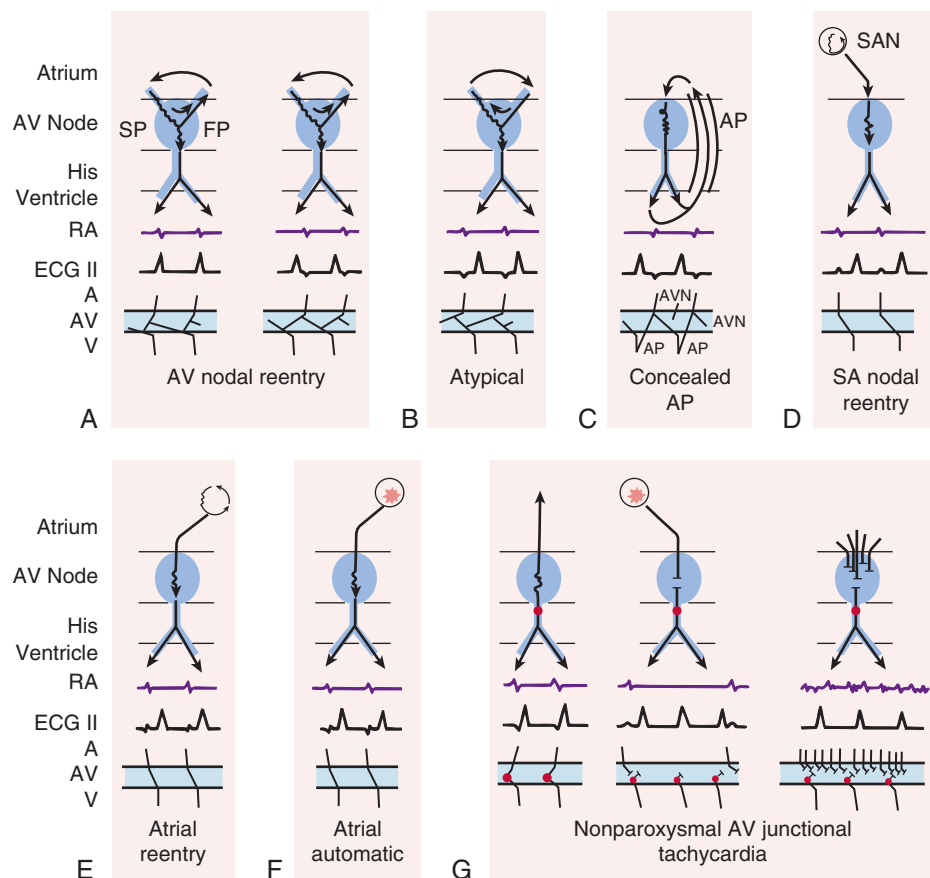

FIGURE 37-8 Diagrammatic representation of various tachycardias. In the upper portion of each example a schematic of the presumed anatomic pathways is shown; in the lower half the ECG and explanatory ladder diagram are depicted. **A**, AV nodal reentry. In the left example, reentrant excitation is drawn with retrograde atrial activity occurring simultaneously with ventricular activity as a result of anterograde conduction over the slow AV nodal pathway (SP) and retrograde conduction over the fast AV nodal pathway (FP). In the right example, atrial activity occurs slightly later than ventricular activity because of retrograde conduction delay. **B**, Atypical AV nodal reentry caused by anterograde conduction over a fast AV nodal pathway and retrograde conduction over a slow AV nodal pathway. **C**, Concealed accessory pathway (AP). Reciprocating tachycardia is caused by anterograde conduction over the AV node (AVN) and retrograde conduction over the accessory pathway. Retrograde P waves occur after the QRS complex. **D**, Sinus nodal reentry. The tachycardia is caused by reentry within the sinus node, which then conducts the impulse to the rest of the heart. SAN = sinoatrial node. **E**, Atrial reentry. Tachycardia is caused by reentry within the atrium, which then conducts the impulse to the rest of the heart. **F**, Automatic atrial tachycardia (the star indicates the origin). Tachycardia is caused by automatic discharge in the atrium, which then conducts the impulse to the rest of the heart; it is difficult to distinguish from atrial reentry. **G**, Various manifestations of nonparoxysmal AV junctional tachycardia are depicted with retrograde atrial capture, AV dissociation with the sinus node in control of the atria, and AV dissociation with atrial fibrillation. The star indicates sinus node discharge. Red circles indicate the site of junctional discharge.

functional in nature is not known. In most examples, the retrograde P wave occurs at the onset of the QRS complex, which clearly excludes the possibility of an accessory pathway. If an accessory pathway in the ventricle were part of the tachycardia circuit, the ventricles would have to be activated anterogradely before the accessory pathway could be activated retrogradely and depolarize the atria, thus placing the retrograde P wave no earlier than 30 milliseconds after onset of the QRS and typically during the ST segment.

In approximately 30% of cases, atrial activation begins at the end of or just after the QRS complex and gives rise to a discrete P wave on the scalar ECG (often appearing as a nubbin of an R in V_1 ; see Fig. 37-8A), whereas in most patients, P waves are not seen because they are buried within the inscription of the QRS complex. In the most common variety of AV nodal reentrant tachycardia (AVNRT), the ventriculoatrial (VA) interval (i.e., the interval between the onset of QRS and the onset of atrial activity) is less than 50% of the R-R interval (a so-called short-RP tachycardia). These VA intervals are longer in patients with tachycardia related to accessory pathways, as well as in those with atypical forms of AV nodal reentry (see Fig. 37-8B).

Slow and Fast Pathways. In most patients, anterograde conduction to the ventricle occurs over the slow pathway and retrograde conduction occurs over the fast pathway, so-called typical AVNRT (see Chapter 33 and Fig. 37-8A, B). To initiate tachycardia, an atrial complex blocks conduction in the fast pathway anterogradely (because

it typically has a longer refractory period relative to the slow pathway), travels to the ventricle over the slow pathway, and returns to the atrium over the previously blocked fast pathway (slow-fast form). The proximal and distal final pathways for this circus movement appear to be located within the AV node, so as currently conceived, the circus movement occurs over the two atrial approaches and the AV node (see Fig. 37-8A, B). The reentrant loop for typical AV nodal reentry is the anterograde slow AV nodal pathway to the final distal common pathway (probably the distal AV node), to the retrograde fast AV nodal pathway, and then to the atrial myocardium. In atypical AV nodal reentry, the reentry occurs in the opposite direction. Less commonly, the reentry pathway can be over two slow pathways or over a slow and intermediate pathway, the so-called slow-slow AV nodal reentry (see Fig. 37-8B). Conduction time in the anterograde slow pathway is a major determinant of the cycle length of the tachycardia.

Dual-Atrioventricular Nodal Pathway

Concept. Evidence supporting the dual-pathway concept is derived from several observations, the most compelling of which is that RF catheter ablation of either the slow pathway or the fast pathway eliminates AV nodal reentry without eliminating AV nodal conduction. Additionally, in these patients a plot of the A_1 - A_2 pathway versus the A_2 - H_2 or the H_1 - H_2 interval shows a discontinuous curve (see Fig. 37-11) because at a crucial A_1 - A_2 interval, the impulse is suddenly blocked in the fast pathway and is conducted with delay over the slow pathway, with sudden prolongation of the A_2 - H_2 (or H_1 - H_2) interval. In general, the A-H interval increases at least 50 milliseconds, with only a 10-millisecond decrease in the coupling interval of the PAC. Less commonly, dual pathways may be manifested by different PR or A-H intervals during sinus rhythm or at identical paced rates or by a sudden jump in the A-H interval during atrial pacing at a constant cycle length. Virtually irrefutable proof of dual AV nodal pathways is the simultaneous propagation in opposite directions of two AV nodal wave fronts without collision (see Chapter 33) or the production of two QRS complexes from one P wave (see Fig. 37-10B) or two P waves from one QRS complex.

Some patients with AV nodal reentry may not have discontinuous refractory period curves, and some patients who do not have AV nodal reentry can exhibit discontinuous refractory curves. In the latter patients, dual AV nodal pathways can be a benign finding. Many of these patients also exhibit discontinuous curves retrogradely. Similar mechanisms of tachycardia can occur in children. Triple AV nodal pathways can be demonstrated in occasional patients.

In less than 5% to 10% of patients with AV nodal reentry, anterograde conduction proceeds over the fast pathway and retrograde conduction over the slow pathway (termed the unusual or atypical form of fast-slow AV nodal reentry), with production of a long VA interval and a relatively short AV interval (generally an AV/VA ratio of less than 0.75; see Fig. 37-8B). The least common form (slow-slow) exhibits a retrograde P wave midway in the cardiac cycle. Finally, it is possible to have tachycardias that use the anterograde slow or fast pathways and conduct retrogradely over an accessory pathway (see later).

Because in some instances either the atria or the ventricles are not needed to maintain AV nodal reentry, spontaneous AV block can occur, particularly at the onset of the arrhythmia, in the AV node distal to the reentry circuit, between the AV node and bundle of His, within the bundle of His, or distal to it (see Chapter 33). Most commonly, when a block appears, it is below the bundle of His, rarely in the upper

common final pathway between the reentry circuit in the AV node and the atrium, and results in dissociation of the atria from the tachycardia. Termination of the tachycardia generally results from a block in the anterogradely conducting slow pathway (weak link), so a retrograde atrial response is not followed by a His or ventricular response.

A functional bundle branch block during AVNRT does not modify the tachycardia significantly.

Retrograde Atrial Activation. The sequence of retrograde atrial activation is normal (also called concentric) during AV nodal reentrant SVT, which means that the earliest site of atrial activation during retrograde conduction over the fast pathway is recorded in the His bundle electrogram, followed by electrograms recorded from the os of the coronary sinus and then spreading to depolarize the rest of the right and left atria. During retrograde conduction over the slow pathway in the atypical type of AV nodal reentry, atrial activation recorded in the proximal coronary sinus precedes atrial activation recorded in the low right atrium, which suggests that the slow and fast pathways can enter the atria at slightly different positions.

Clinical Features

AV nodal reentry commonly occurs in patients without structural heart disease, often in the late teens or 20s. Symptoms frequently accompany the tachycardia and range from feelings of palpitations, nervousness, and anxiety to angina, heart failure, syncope, or shock, depending on the duration and rate of the tachycardia and the presence of structural heart disease. Tachycardia can cause syncope because of the rapid ventricular rate, reduced cardiac output, and cerebral circulation or because of asystole when the tachycardia terminates as a result of tachycardia-induced depression of sinus node automaticity. The prognosis for patients without heart disease is usually good.

FIGURE 37-9 Twelve-lead ECG of AVNRT. **A**, During tachycardia, a pseudo-r' is seen in lead V₁ (arrowhead), and pseudo-S waves (arrowhead) are seen in leads II, III, and aVF. **B**, These waves become more obvious when compared with the QRS complexes during sinus rhythm.

FIGURE 37-10 **A**, Initiation of AVNRT in a patient with dual AV nodal pathways. The upper and lower panels show the last two paced beats of a train of stimuli delivered to the coronary sinus at a pacing cycle length of 500 milliseconds. The results of premature atrial stimulation at an S₁-S₂ interval of 250 milliseconds on two occasions are shown. **Upper panel**, S₂ was conducted to the ventricle with an A-H interval of 170 milliseconds and was then followed by a sinus beat. **Lower panel**, S₂ was conducted with an A-H interval of 300 milliseconds and initiated AV nodal reentry. Note that the retrograde atrial activity occurs (arrow) before the onset of ventricular septal depolarization and is superimposed on the QRS complex. Retrograde atrial activity begins first in the low right atrium (HBE lead) and then progresses to the high right atrium (RA) and coronary sinus (CS) recordings. **B**, Two QRS complexes in response to a single atrial premature complex. After a basic train of S₁ stimuli at 600 milliseconds, an S₂ at 440 milliseconds is introduced. The first QRS complex in response to S₂ occurs after a short A-H interval (95 msec) caused by anterograde conduction over the fast AV nodal pathway. The first QRS complex is labeled 1 (in lead V₁). The second QRS complex in response to the S₂ stimulus (labeled 2) follows a long A-H interval (430 msec) caused by anterograde conduction over the slow AV nodal pathway. DCS = distal coronary sinus; HRA = high right atrium; MCS = mid coronary sinus; PCS = proximal coronary sinus; RV = right ventricle.

FIGURE 37-11 H₁-H₂ intervals (left) and A₂-H₂ intervals (right) at various A₁-A₂ intervals with a discontinuous AV nodal curve. At a critical A₁-A₂ interval, the H₁-H₂ and A₂-H₂ intervals increase markedly. At the break in the curves, AVNRT is initiated.

Management

ACUTE ATTACK. Management of AVNRT depends on the underlying heart disease, how well the tachycardia is tolerated, and the natural history of previous attacks in the individual patient. For some patients, rest, reassurance, and sedation may be all that is required to abort an occasional attack. Vagal maneuvers, including carotid sinus massage, the Valsalva and Müller maneuvers, gagging, and occasionally exposure of the face to ice water, serve as the first line of therapy. These maneuvers can slow the tachycardia rate slightly, which may then speed up to the original rate after cessation of the attempt, or can terminate it. If vagal maneuvers fail, adenosine (see Chapter 35), 6 to 12 mg administered rapidly intravenously, is the initial drug of choice and successfully terminates (within 1 minute) the tachycardia in about 90% of cases. Verapamil (see Chapter 35), 5 to 10 mg intravenously, or diltiazem, 0.25 to 0.35 mg/kg intravenously, terminates AV nodal reentry successfully in about 2 minutes in approximately 90% of cases when simple vagal maneuvers and adenosine fail. Beta-adrenergic receptor blockers can be effective but are not generally used as first-line therapy because adenosine, verapamil, and diltiazem are more effective and faster acting. Calcium antagonists, beta adrenoceptor blockers, and adenosine normally depress conduction in the anterogradely conducting slow AV nodal pathway, whereas class IA and IC drugs (not usually required) depress conduction in the retrogradely conducting fast pathway (Table 37-3). DC cardioversion should generally be attempted before use of these latter agents, which are more often administered to prevent recurrence.

Rarely, if AVNRT results in hemodynamic compromise and is refractory to adenosine, DC cardioversion may be indicated. DC shock in

they are rarely needed unless the patient is also hypotensive.

PREVENTION OF RECURRENCES. Initially, one must decide whether the frequency and severity of the attacks warrant long-term therapy. If the attacks are infrequent, well tolerated, and short and either terminate spontaneously or are easily terminated by the patient, no prophylactic therapy may be necessary. Longer and more frequent attacks can be treated with drugs, although ablation is an effective first-line alternative. In patients with syncope or near syncope, ablation should be considered as first-line therapy. A long-acting calcium antagonist or a long-acting beta adrenoceptor blocker is a reasonable initial choice for drug therapy. The clinical situation and potential contraindications, such as beta blockers in an asthmatic patient, usually dictate the selection.

RADIOFREQUENCY ABLATION. RF ablation is more than 95% effective in achieving long-term cure, with a low incidence of complications, and should be considered early in the management of patients with symptomatic recurrent episodes of AV nodal reentry, especially for patients who do not wish to take drugs, who are drug intolerant, or in whom drugs are ineffective.

Accessory Atrioventricular Pathways

Accessory pathways are fibers that connect the atrium or AV node to the ventricle outside the normal AV nodal-His-Purkinje conduction system. These pathways can conduct impulses in the forward (anterograde from the atrium to the ventricle) or reverse (retrograde from the ventricle to the atrium) direction and are potential substrates for reentrant tachycardias (AV reciprocating tachycardia). When the pathway is capable of anterograde conduction, the ventricle can be depolarized in part by the accessory pathway (outside the normal His-Purkinje system) and produces a QRS complex that is preexcited (i.e., with a delta wave; see later). When ventricular preexcitation is present and the symptoms are compatible with tachycardia, the patient is said to have WPW syndrome. In some cases the pathways are able to conduct only in the retrograde direction; thus, they do not produce any ventricular preexcitation and are said to be concealed.

Reentry over a Concealed (Retrograde-Only) Accessory Pathway

Electrocardiographic Recognition

The presence of an accessory pathway that conducts unidirectionally from the ventricle to the atrium but not in the reverse direction is not apparent by analysis of the ECG during sinus rhythm because the ventricle is not preexcited (Fig. 37-12). Therefore, electrocardiographic manifestations of WPW syndrome are absent, and the

patients who have received excessive amounts of digitalis can be dangerous and result in serious postshock ventricular arrhythmias (see Chapter 35). DC shock, synchronized to the QRS complex to avoid precipitation of ventricular fibrillation (VF), successfully terminates AV nodal reentry with energy in the range of 10 to 50 J; higher energy may be required in some cases. If DC shock is contraindicated or if pacing wires are already in place (postoperatively or if the patient has a permanent pacemaker), competitive atrial or ventricular pacing can restore sinus rhythm.

Pressor drugs can terminate AV nodal reentry by inducing reflex vagal stimulation mediated by baroreceptors in the carotid sinus and aorta when systolic blood pressure is acutely elevated to levels of approximately 180 mm Hg, but

TABLE 37-3 Drugs That Slow Conduction in and Prolong Refractoriness of the Accessory Pathway and Atrioventricular Node

AFFECTED TISSUE	DRUGS

AV node	Class II Class IV Adenosine Digitalis
Both	Class IC Class III (amiodarone)

FIGURE 37-12 Atrial preexcitation during AV reciprocating tachycardia in a patient with a concealed accessory pathway. No evidence of accessory pathway conduction is present in the two sinus-initiated beats shown in **A**. A premature stimulus in the coronary sinus (S) precipitates SVT at a cycle length of approximately 330 milliseconds. The retrograde atrial activation sequence begins first in the distal coronary sinus (A', DCS), followed by activation recorded in the proximal coronary sinus (PCS), low right atrium (HBE), and then the high right atrium (not shown). The QRS complex is normal and identical to the sinus-initiated QRS complex. (The terminal portion is slightly deformed by superimposition of the retrograde atrial recording.) Note that the RP interval is short and the PR interval is long. The shortest VA interval exceeds 65 milliseconds, consistent with conduction over a retrogradely conducting AV pathway. **B**, Premature ventricular stimulation at a time when the His bundle is still refractory from anterograde activation during tachycardia shortens the A-A interval from 330 to 305 milliseconds without a change in the retrograde atrial activation sequence. (Note that no change occurs in the H-H interval when the RV stimulus [S] is delivered. H-H intervals are in msec in the HBE lead.) Thus the ventricular stimulus, despite His bundle refractoriness, still reaches the atrium and produces an identical retrograde atrial activation sequence. The only way that this finding can be explained is by conduction over a retrogradely conducting accessory pathway. Therefore the patient has a concealed accessory pathway with WPW syndrome. HRA = high right atrium; RV = right ventricle.

accessory pathway is said to be concealed. Because the mechanism responsible for most tachycardias in patients with WPW syndrome is macroreentry caused by anterograde conduction over the AV node–His bundle pathway and retrograde conduction over an accessory pathway, the accessory pathway, even if it conducts only retrogradely, can still participate in the reentrant circuit and cause an AV reciprocating tachycardia. On electrocardiographic examination, a tachycardia resulting from this mechanism can be suspected when

the QRS complex is normal and the retrograde P wave occurs after completion of the QRS complex, in the ST segment, or early in the T wave (see Fig. 37-8C). Sometimes the P wave is not clearly visible and can result in depression of the ST segment; when this is seen during tachycardia, the mechanism of the arrhythmia is most often reentry involving an accessory pathway (AV reentrant tachycardia). In addition, in this setting the ST depression that occurs only during the tachycardia (resolves with termination of the tachycardia) does not indicate ischemia in the absence of other evidence of ischemia (chest pain, enzyme elevation, known coronary disease).

The P wave follows the QRS complex during tachycardia because the ventricle must be activated before the propagating impulse can enter the accessory pathway and excite the atria retrogradely. Therefore, the retrograde P wave must occur after ventricular excitation, in contrast to AV nodal reentry, in which the atria are usually excited during ventricular activation (see Fig. 37-8A). Also, the contour of the retrograde P wave can differ from that of the usual retrograde P wave because the atria may be activated eccentrically, that is, in a manner other than the normal retrograde activation sequence, which starts at the low right atrial septum as in AV nodal reentry. This eccentric activation occurs because the concealed accessory pathway in most cases is left sided (i.e., inserts into the left atrium), which makes the left atrium the first site of retrograde atrial activation and causes the retrograde P wave to be negative in lead I (see Fig. 37-12).

Finally, because the tachycardia circuit involves the ventricles, if a functional bundle branch block occurs in the same ventricle in which the accessory pathway is located, the VA interval and cycle length of the tachycardia can become longer (Fig. 37-13). This important change ensues because the bundle branch block lengthens the reentrant circuit (see Preexcitation Syndrome). For example, the normal activation sequence for a reciprocating tachycardia circuit with a left-sided accessory pathway but without a functional bundle branch block progresses from the atrium to the AV node–His bundle, to the right and left ventricles, to the accessory pathway, and then to the atrium. However, during a functional left bundle branch block, for example, the tachycardia circuit travels from the atrium to the AV node–His bundle, to the right ventricle, to the septum, to the left ventricle, to the accessory pathway, and then back to the atrium. This increase in the VA interval provides definitive proof that the ventricle and accessory pathway are part of the reentry circuit. The additional time required for the impulse to travel across the septum from the right to the left ventricle before reaching the accessory pathway and atrium lengthens the VA interval, which consequently lengthens the cycle of the tachycardia by an equal amount, assuming that no other changes in conduction times occur within the circuit. Thus, lengthening of the tachycardia cycle by more than 30 milliseconds during an ipsilateral functional bundle branch block is diagnostic of a free wall accessory pathway if the lengthening can be shown to be caused by VA prolongation only and not by prolongation of the H-V interval (which can develop with the appearance of a bundle branch block). In an occasional patient, the increase in cycle length because of prolongation of VA conduction can be nullified by a simultaneous decrease in the PR (A-H) interval.

The presence of an ipsilateral bundle branch block can facilitate reentry and cause an incessant AV reentrant tachycardia. A functional bundle branch block in the ventricle contralateral to the accessory pathway does not lengthen the tachycardia cycle if the H-V interval does not lengthen.

Septal Accessory Pathway

An exception to these observations occurs in patients with a concealed septal accessory pathway. First, retrograde atrial activation is normal (concentric) because it occurs retrogradely up the septum. Second, the VA interval and cycle length of the tachycardia increase 25 milliseconds or less with the development of an ipsilateral functional bundle branch block.

Vagal maneuvers, by acting predominantly on the AV node, produce a response on AV reentry similar to AV nodal reentry, and the tachycardia can transiently slow and sometimes terminate. In general, termination occurs in the anterograde direction, so the last retrograde P wave fails to conduct to the ventricle.

FIGURE 37-13 A, Recording of depolarization of an accessory pathway (AP) with a catheter electrode. The first QRS complex illustrates conduction over the AP. On the scalar ECG, a short PR interval and delta wave (best seen in leads I and V_1) are apparent. His-bundle activation is buried within the ventricular complex. In the following complex, conduction has been blocked over the AP, and a normal QRS complex results. His-bundle activation clearly precedes the onset of ventricular depolarization by 45 milliseconds. The A-H interval for this complex is 90 milliseconds. **B**, Influence of a functional ipsilateral bundle branch block on the VA interval during AV reciprocating tachycardia. Partial preexcitation can be noted in the sinus-initiated complex (first complex). Two premature ventricular stimuli (S_1 , S_2) initiate a sustained SVT that persists with a left bundle branch block for several complexes before finally reverting to normal. The retrograde atrial activation sequence is recorded first in the proximal coronary sinus lead (arrowhead, PCS), then in the distal coronary sinus lead (DCS) and low right atrium (HBE), and then high in the right atrium (HRA). During the functional bundle branch block, the VA interval in the PCS lead is 140 milliseconds, which shortens to 110 milliseconds when the QRS complex reverts to normal. Such behavior is characteristic of a left-sided accessory pathway with prolongation of the reentrant pathway by the functional left bundle branch block. (**A**, From Prystowsky EN, Browne KF, Zipes DP: Intracardiac recording by catheter electrode of accessory pathway depolarization. *J Am Coll Cardiol* 1:468, 1983.)

Electrophysiologic Features. EP criteria supporting the diagnosis of tachycardia involving reentry over a concealed accessory pathway include the fact that initiation of tachycardia depends on a critical degree of AV delay (necessary to allow time for the accessory pathway to recover excitability so that it can conduct retrogradely), but the delay can be in the AV node or His-Purkinje system; that is, a critical degree of A-H delay is not necessary (as it is in AV nodal reentry). On occasion, a tachycardia can start with little or no measurable lengthening of AV nodal or His-Purkinje conduction time. The AV nodal refractory period curve is smooth, in contrast to the discontinuous curve found in many patients with AV nodal reentry. Dual AV nodal pathways can occasionally be noted as a concomitant but unrelated finding.

Diagnosis of Accessory Pathways

Diagnosis can be made by demonstrating that during ventricular pacing, premature ventricular stimulation activates the atria before retrograde depolarization of the His bundle, thus indicating that the impulse reached the atria before it depolarized the His bundle and therefore must have traveled a different pathway. Also, if the ventricles can be stimulated prematurely during tachycardia at a time when the His bundle is refractory and the impulse still conducts to the atrium, the retrograde propagation traveled to the atrium over a pathway other than the bundle of His (see Fig. 37-12B). If the PVC depolarizes the atria without lengthening the VA interval and with the same retrograde atrial activation sequence, one assumes that the stimulation site (i.e., ventricle) is within the reentrant circuit without intervening His-Purkinje or AV nodal tissue that might increase the VA interval and therefore the A-A interval. In addition, if a PVC delivered at a time when the His bundle is refractory terminates the tachycardia without activating the atria retrogradely, it must have invaded and blocked conduction in an accessory pathway and is therefore diagnostic of an accessory pathway participating in the reentrant circuit.

The VA interval (a measurement of conduction over the accessory pathway) is generally constant over a wide range of ventricular paced rates and coupling intervals of PVCs, as well as during the tachycardia in the absence of aberration. Similar short VA intervals can be observed in some patients during AV nodal reentry, but if the VA conduction time or RP interval is the same during tachycardia and ventricular pacing at comparable rates, an accessory pathway is almost certainly present. The VA interval is usually less than 50% of

the R-R interval. The tachycardia can easily be initiated after premature ventricular stimulation that conducts retrogradely in the accessory pathway but blocks conduction in the AV node or His bundle. Atria and ventricles are required components of the macroreentrant circuit; therefore, continuation of the tachycardia in the presence of an AV or VA block excludes an accessory AV pathway as part of the reentrant circuit.

Clinical Features

Concealed accessory pathways are estimated to be present in approximately 30% of patients with apparent SVT referred for EP evaluation. Most of these accessory pathways are located between the left ventricle and left atrium or in the posteroseptal area, less commonly between the right ventricle and right atrium. It is important to be aware of a concealed accessory pathway as a possible cause of apparently routine SVT because the therapeutic response may at times not follow the usual guidelines. Tachycardia rates tend to be somewhat faster than those occurring in AV nodal reentry (200 beats/min), but a great deal of overlap exists between the two groups.

Syncope can occur because the rapid ventricular rate fails to provide adequate cerebral circulation or because the tachyarrhythmia depresses the sinus pacemaker and causes a period of asystole when the tachyarrhythmia terminates. Physical examination reveals an unvarying, regular ventricular rhythm, with constant intensity of the first heart sound. Jugular venous pressure can be elevated (large A wave), but the waveform generally remains constant.

Management

The therapeutic approach to termination of this form of tachycardia acutely is as outlined for AV nodal reentry because the AV node is a critical part of the circuit here as well. It is necessary to achieve block of a single impulse from the atrium to the ventricle or from the ventricle to the atrium. In general, the most successful method is to produce a transient AV nodal block; therefore, vagal maneuvers and intravenous administration of adenosine, verapamil, or diltiazem and beta blockers are acceptable choices. RF catheter ablation and antiarrhythmic agents that prolong the activation time or refractory period in the accessory pathway need to be considered for chronic prophylactic therapy, similar to what was discussed for reciprocating tachycardias associated with preexcitation syndrome. RF catheter ablation is curative, has low risk, and should be considered early for symptomatic patients (see Chapter 35). The presence of atrial fibrillation

in patients with a concealed accessory pathway should not be a greater therapeutic challenge than in patients who do not have such a pathway because anterograde AV conduction occurs only over the AV node and not over an accessory pathway. Intravenous administration of verapamil is not contraindicated. However, in some circumstances, such as catecholamine stimulation, anterograde conduction can occur in the apparently concealed accessory pathway.

Preexcitation Syndrome

Electrocardiographic Recognition

Preexcitation, or the WPW abnormality on the ECG, occurs when the atrial impulse activates the entire ventricle or some part of it or the ventricular impulse activates the entire atrium or some part of it earlier than would be expected if the impulse traveled only by way of the normal specialized conduction system (**Fig. 37-14**). This

FIGURE 37-14 **A**, Right anteroseptal accessory pathway. The 12-lead ECG characteristically exhibits a normal to inferior axis. The delta wave is upright in leads I, II, and aVF; isoelectric or negative in aVL; and negative in aVR. There is an rS in V₁ and V₂. **B**, Right posteroseptal accessory pathway. Negative delta waves in leads II, III, and aVF, upright in I and aVL, localize this pathway to the posteroseptal region. The negative delta wave in V₁ with sharp transition to an upright delta wave in V₂ pinpoints it to the right posteroseptal area. Atrial fibrillation is present. **C**, Left lateral accessory pathway. A positive delta wave in the anterior precordial leads and in leads II, III, and aVF, positive or isoelectric in leads I and aVL, and isoelectric or negative in leads V₅ and V₆ are typical of a left lateral accessory pathway. Also notice the relatively small amount of preexcitation typical of left lateral accessory pathways during sinus rhythm, which is caused by the sinus impulse taking longer to travel through the entire right and left atria to the accessory pathway than it does from the sinus node to the AV node.

Continued

FIGURE 37-14, cont'd D. Right free wall accessory pathway. The predominantly negative delta wave in V₁ and the axis more leftward than in **A** indicate the presence of a right free wall accessory pathway. **E.** Stepwise algorithm to determine the general location of accessory pathways on a 12-lead ECG with preexcitation. The algorithm assumes that some preexcitation is present and uses the delta wave polarity (determined as the first 20 msec after the onset of the delta wave on the ECG) and QRS morphology. QRSd = QRS duration. (**E.** From Fox DJ, Klein GJ, Skanes AC, et al: How to identify the location of an accessory pathway by the 12-lead ECG. *Heart Rhythm* 5:1763, 2008.)

premature activation is caused by muscle connections composed of working myocardial fibers that exist outside the specialized conducting tissue and connect the atrium and ventricle while bypassing AV nodal conduction delay. They are referred to as accessory AV pathways or connections and are responsible for the most common variety of preexcitation (incidentally noted in other species such as monkeys, dogs, and cats). The term *syndrome* is attached to this disorder when tachyarrhythmias occur as a result of the accessory pathway. Three basic features typify the electrocardiographic abnormalities in patients with the usual form of WPW conduction caused by an AV connection: (1) PR interval less than 120 milliseconds during sinus rhythm; (2) QRS complex duration exceeding 120 milliseconds with a slurred, slowly rising onset of the QRS in some leads (delta wave) and usually a normal terminal QRS portion; and (3) secondary ST-T wave changes that are generally directed in an opposite direction to the major delta and QRS vectors. Analysis of the scalar ECG can be used to localize the accessory pathway (see Fig. 37-14D).¹¹

In WPW syndrome, the most common tachycardia is characterized by a normal QRS, a regular rhythm, ventricular rates of 150 to 250 beats/minute (generally faster than AV nodal reentry), and sudden onset and termination, in most respects behaving like the tachycardia described for conduction over a concealed pathway (see earlier). The major difference between the two is the capacity for anterograde conduction over the accessory pathway during atrial flutter or atrial fibrillation (see later).

Variants. Various other anatomic substrates exist and provide the basis for different electrocardiographic manifestations of several variations of preexcitation syndrome, as summarized in Table 37-4 (Fig. 37-15). Fibers from the atrium to the His bundle bypassing the physiologic delay of the AV node are called atriohisian tracts (see Fig. 37-15B) and are associated with a short PR interval and a normal QRS complex. Although demonstrated anatomically (see later), the EP significance of these tracts in the genesis of tachycardias with a short PR interval and a normal QRS complex (so-called Lown-Ganong-Levine [LGL] syndrome) remains to be established. Indeed, evidence does not

TABLE 37-4 Accessory Pathway Variants

PATHWAY TYPE	PR	QRS	TACHYCARDIA	COMMENTS
Atriohisian	Short	Normal	Unlikely	
Atriofascicular	Normal	Preexcitation (LBBB, superior axis)	Antidromic AVRT	Preexcitation with fast atrial rates or atrial extrastimuli
Nodofascicular	Normal	Preexcitation (LBBB, superior axis)	Antidromic AVRT; AVNRT with bystander activation of the AP	Preexcitation with fast atrial rates or atrial extrastimuli
Fasciculoventricular	Normal	Anomalous (short H-V)	None	

AP = accessory pathway; AVRT = atrioventricular reentrant (reciprocating) tachycardia; LBBB = left bundle branch block.

FIGURE 37-15 Schematic representation of accessory pathways. **A**, The “usual” AV accessory pathway giving rise to most clinical manifestations of tachycardia associated with WPW syndrome. **B**, The very uncommon atriohisian accessory pathway. If LGL syndrome is present, it would have this type of anatomy, which has been demonstrated histopathologically on occasion. **C**, Nodovertricular pathways, original concept, in which anterograde conduction travels down the accessory pathway with retrograde conduction in the bundle branch–His bundle–AV node (see later). **D**, Fasciculoventricular connections, which are not thought to play an important role in the genesis of tachycardias. **E**, Current concept of the nodofascicular accessory pathway, in which the accessory pathway is an AV communication with AV node–like properties. Sinus rhythm results in a fusion QRS complex, as in the usual form of WPW syndrome shown in **A**. Maximum preexcitation results in ventricular activation over the accessory pathway, and the His bundle is activated retrogradely. During reciprocating tachycardia, anterograde conduction occurs over the accessory pathway and retrograde conduction over the normal pathway. LBBB = left bundle branch block; RBBB = right bundle branch block. (**E**, From Benditt DG, Milstein S: Nodovertricular accessory connection: A misnomer or a structural/functional spectrum? *J Cardiovasc Electrophysiol* 1:231, 1990.)

support the presence of a specific LGL syndrome consisting of a short PR interval, normal QRS complex, and tachycardias related to an atriohisian bypass tract.

Another variant of accessory pathway conduction is that caused by atriofascicular or nodofascicular accessory pathways. These fibers result in a unique AV conduction pattern, sometimes referred to as Mahaim conduction, characterized by the development of ventricular preexcitation (widened QRS and short H-V interval) with a progressive increase in the AV interval in response to atrial overdrive pacing, as opposed to the behavior of the usual accessory pathway in which

preexcitation occurs with short AV intervals (**Fig. 37-16**). Because the accessory pathways responsible for this conduction pattern usually insert into the right bundle branch, preexcitation generally results in a left bundle branch block pattern. This phenomenon can be caused by fibers passing from the AV node to the ventricle, called nodovertricular fibers (or nodofascicular if the insertion is into the right bundle branch rather than into ventricular muscle; see **Fig. 37-15C**). For nodovertricular connections, the PR interval can be normal or short, and the QRS complex is a fusion beat. This pattern of preexcitation can also result from atriofascicular accessory pathways. These fibers almost always represent a duplication of the AV node and the distal conducting system and are located in the right ventricular (RV) free wall. The apical end lies close to the lateral tricuspid annulus and conducts slowly, with AV node–like properties. After a long course, the distal portion of these fibers, which conducts rapidly, inserts into the distal right bundle branch or the apical region of the right ventricle. No preexcitation is generally apparent during sinus rhythm, but it can be exposed by premature right atrial stimulation. The usual absence of retrograde conduction in these pathways produces only an antidromic AV reentry tachycardia (“preexcited” tachycardia) characterized by anterograde conduction over the accessory pathway and retrograde conduction over the right bundle branch–His bundle–AV node, thus making the atrium a necessary part of the circuit. The preexcited tachycardia has a left bundle branch block pattern, long AV interval (because of the long conduction time over the accessory pathway), and short VA interval. A right bundle branch block can be proarrhythmic by increasing the length of the tachycardia circuit (the VA interval is prolonged because of a delay in retrograde activation of the His bundle), and the tachycardia can become incessant.

In patients with an atriohisian tract, the QRS complex would theoretically remain normal and the short A-H interval would be fixed or would show very little increase during atrial pacing at more rapid rates. This response is uncommon. Rapid atrial pacing in patients who have nodovertricular or nodofascicular connections shortens the H-V interval and widens the QRS complex, with production of a left bundle branch block contour, but in contrast to the situation in patients who have an AV connection (**Fig. 37-17**), the AV interval also lengthens. In patients with fasciculoventricular connections, the H-V interval remains short and the QRS complex unchanged and anomalous during rapid atrial pacing.

Electrophysiologic Features of Preexcitation. If the accessory pathway is capable of anterograde conduction, two parallel routes of AV conduction are possible, one subject to physiologic delay over the AV node and the other passing directly without delay from the atrium to the ventricle (see **Figs. 37-13 and 37-15 through 37-22; Fig. e37-3**). This direct route of conduction produces the typical QRS complex, which is a fusion beat as a result of depolarization of the ventricle, in part by the wave front traveling over the accessory pathway and in part by the wave front traveling over the normal AV node–His bundle route. The delta wave represents ventricular activation from input over the accessory pathway. The extent of the contribution to ventricular depolarization by the wave fronts over each route depends on their relative activation times. If AV nodal conduction delay occurs because of a rapid atrial pacing rate or PAC, for example, more of the ventricle becomes activated over the accessory pathway and the QRS complex becomes more anomalous in contour. Total activation of the ventricle over the accessory pathway can occur if the AV nodal conduction delay is sufficiently long. In contrast, if the accessory pathway is relatively far from the sinus node, for example, a left lateral accessory pathway, or if the AV nodal conduction time is relatively short, more of the ventricle can be activated by conduction over the normal pathway (see **Fig. 37-17**). The normal fusion beat during sinus rhythm has a short H-V interval, or His-bundle activation actually begins after the onset of ventricular

FIGURE e37-3 AV reciprocating tachycardia disorganizing into atrial fibrillation. During sustained AV reciprocating tachycardia at a cycle length of approximately 265 milliseconds, the retrograde atrial activation sequence began first in the right paraseptal region (not shown in this example; location proved at surgery) and was then recorded in the proximal coronary sinus (PCS) electrogram, followed by atrial activity in the distal coronary sinus (DCS), in the low right atrium recorded in the His bundle lead, and then in the high right atrium. Spontaneously, the atrial activation sequence becomes irregular (after the last A') and atrial fibrillation begins. Note that the last QRS complex reflects conduction over the accessory pathway. Such a transformation occurred repeatedly in this patient and was associated with quickening of the ventricular rate. Atrial fibrillation did not recur following surgical interruption of the accessory pathway. HBE = His bundle electrogram; RA = right atrium; RV = right ventricle.

FIGURE 37-16 Development of preexcitation over an atriofascicular accessory pathway. During atrial pacing (S) on the left side of the figure, conduction occurs down the AV node as evidenced by a normal-appearing QRS complex and a normal H-V interval. The stimulus marked by the arrowhead conducts the impulse down an atriofascicular fiber, which results in a preexcited QRS, as evidenced by a widened QRS and short H-V interval. CS = coronary sinus; HRA = high right atrium; RV = right ventricle.

depolarization because part of the atrial impulse bypasses the AV node and activates the ventricle early, at a time when the atrial impulse traveling the normal route just reaches the His bundle. This finding of a short or negative H-V interval occurs only during conduction over an accessory pathway or from retrograde His activation during a complex originating in the ventricle, such as VT.

accessory pathway, which blocks conduction in an anterograde direction, recovers excitability in time to be activated after the QRS complex in a retrograde direction, thereby completing the reentrant loop.

Much less commonly, patients can have tachycardias called antidromic tachycardias, during which anterograde conduction occurs

Pacing the atrium at rapid rates, at premature intervals, or from a site close to the atrial insertion of the accessory pathway accentuates the anomalous activation of the ventricles and shortens the H-V interval even more (His activation may become buried in the ventricular electrogram, as shown in Fig. 37-17B). The position of the accessory pathway can be determined by careful analysis of the spatial direction of the delta wave on the 12-lead ECG in maximally preexcited beats (see Fig. 37-14). T wave abnormalities can occur after the disappearance of preexcitation, with orientation of the T wave according to the site of preexcitation (T wave memory).

Accessory Pathway Conduction. Even though the accessory pathway conducts more rapidly than the AV node (conduction velocity is faster in the accessory pathway), the accessory pathway usually has a longer refractory period during long cycle lengths (e.g., sinus rhythm); that is, it takes longer for the accessory pathway than the AV node to recover excitability. Consequently, a PAC can occur sufficiently early to block conduction anterogradely in the accessory pathway and conduct to the ventricle only over the normal AV node–His bundle (see Fig. 37-18A, B). The resultant H-V interval and QRS complex become normal. Such an event can initiate the most common type of reciprocating tachycardia, one characterized by anterograde conduction over the normal pathway and retrograde conduction over the accessory pathway (orthodromic AV reciprocating tachycardia; see Fig. 37-18). The

FIGURE 37-17 Atrial pacing at different atrial sites illustrating different conduction over the accessory pathway. **A**, High right atrial (HRA) pacing at a cycle length of 500 milliseconds produces anomalous activation of the ventricle (note the upright QRS complex in V_1) and a stimulus-delta interval of 155 milliseconds ($S-\delta$ 155). This interval indicates that the time from the onset of the stimulus to the beginning of the QRS complex is relatively long because the stimulus is delivered at a fairly large distance from the accessory pathway. Note that His-bundle activation (H) occurs at about the onset of the QRS complex. **B**, Atrial pacing occurs through the distal coronary sinus electrode (DCS). At the same pacing cycle length, DCS pacing results in more anomalous ventricular activation and a shorter stimulus-delta interval (80 msec). His-bundle activation is now buried within the inscription of the ventricular electrogram in the low right atrium (His bundle electrogram [HBE] lead). **C**, Pacing from the proximal coronary sinus electrode (PCS) results in the shortest stimulus-delta interval (45 msec); such an interval indicates that the pacing stimulus is being delivered very close to the atrial insertion of the accessory pathway, which in this case is located in the left posteroseptal region of the AV groove. RV = right ventricle.

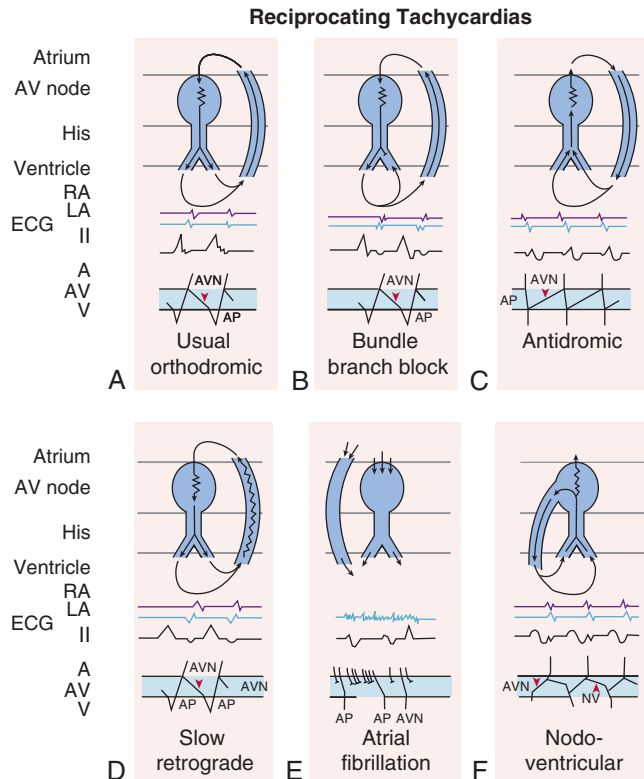

FIGURE 37-18 Schematic diagram of tachycardias associated with accessory pathways. **A**, Orthodromic tachycardia with anterograde conduction (arrowhead) over the AV node–His bundle route and retrograde conduction over the accessory pathway (left sided for this example, as depicted by left atrial activation preceding right atrial activation). **B**, Orthodromic tachycardia and ipsilateral functional bundle branch block. **C**, Antidromic tachycardia with anterograde conduction over the accessory pathway and retrograde conduction (arrowhead) over the AV node–His bundle. **D**, Orthodromic tachycardia with a slowly conducting accessory pathway (arrowhead). **E**, Atrial fibrillation with the accessory pathway as a bystander. **F**, Anterograde conduction over a portion of the AV node and a nodoventricular (NV) pathway and retrograde conduction over the AV node (arrowheads). AP = accessory pathway; AVN = atrioventricular node; LA = left atrium; RA = right atrium.

over the accessory pathway and retrograde conduction over the AV node. The resultant QRS complex is abnormal because of total ventricular activation over the accessory pathway (see Fig. 37-19; also see Fig. 37-18C). In both tachycardias, the accessory pathway is an obligatory part of the reentrant circuit. In patients with bidirectional conduction over the accessory pathway, different fibers can be used anterogradely and retrogradely.

A small percentage of patients have multiple accessory pathways, often suggested by various clues on the ECG, and on occasion, tachycardia can be caused by a reentrant loop conducting anterogradely over one accessory pathway and retrogradely over the other. Fifteen percent to 20% of patients may exhibit AV nodal echoes or AV nodal reentry after interruption of the accessory pathway.

Permanent Form of Atrioventricular Junctional Reciprocating Tachycardia. An incessant form of SVT has been recognized that generally occurs with a long RP interval that exceeds the PR interval (see Figs. 37-20 and 37-21). Usually, a posteroseptal accessory pathway (most often RV but other locations as well) that conducts very slowly, possibly because of a long and tortuous route, appears to be responsible. Tachycardia is maintained by anterograde AV nodal conduction and retrograde conduction over the accessory pathway (see Fig. 37-18D). Although anterograde conduction over this pathway has been demonstrated, the long anterograde conduction time over the accessory pathway ordinarily prevents the electrocardiographic manifestations of accessory pathway conduction during sinus rhythm. Therefore, during sinus rhythm, the QRS duration is prolonged from conduction over this accessory pathway only when conduction times through the AV node–His bundle exceed those in the accessory pathway.

Recognition of Accessory Pathways. When retrograde atrial activation during tachycardia occurs over an accessory pathway that connects the left atrium to the left ventricle, the earliest retrograde activity is recorded from a left atrial electrode usually positioned in the coronary sinus (see Fig. 37-12). When retrograde atrial activation during tachycardia occurs over an accessory pathway that connects the right ventricle to the right atrium, the earliest retrograde atrial activity is generally recorded from a lateral right atrial electrode. Participation of a septal accessory pathway creates the earliest retrograde atrial activation in the low right portion of the atrium situated near the septum, anterior or posterior, depending on the insertion site. These mapping techniques provide an accurate assessment of the position of the accessory pathway, which can be anywhere in the AV groove except in the intervalvular trigone between the mitral valve and the aortic valve annuli. Recording of electrical activity directly from the accessory pathway obviously provides precise localization.

It may be difficult to distinguish AV nodal reentry from participation of a septal accessory connection by use of the retrograde sequence of atrial activation because activation sequences during both tachycardias are similar. Other approaches to demonstrate retrograde atrial activation over the accessory pathway must be tried and can be accomplished by inducing PVCs during tachycardia to determine whether retrograde atrial excitation can occur from the ventricle at a time when the His bundle is refractory (see Fig. 37-17B). VA conduction cannot occur over the normal conduction system because the His bundle is refractory, so an accessory pathway must be present for the atria to become excited. No patient with a reciprocating tachycardia from an accessory AV pathway has a VA interval of less than 70 milliseconds—this is measured from the onset of ventricular depolarization to the onset of the earliest atrial activity recorded on an esophageal lead—or a VA interval of less than 95 milliseconds when it is measured to the high right part of the atrium. In contrast, in most patients with reentry in the AV node, intervals from the onset of ventricular activity to the earliest onset of atrial activity recorded in the esophageal lead are less than 70 milliseconds.

Other Forms of Tachycardia in Patients with Wolff-Parkinson-White Syndrome

Patients can have other types of tachycardia during which the accessory pathway is a bystander, that is, uninvolved in the mechanism responsible for the tachycardia, such as AV nodal reentry or an atrial tachycardia that conducts to the ventricle over the accessory pathway. In patients with atrial flutter or atrial fibrillation, the accessory pathway is not a requisite part of the mechanism responsible for tachycardia, and the flutter or fibrillation occurs in the atrium unrelated to the accessory pathway (see Fig. 37-18E). Propagation to the ventricle during atrial flutter or atrial fibrillation can therefore occur over the normal AV node–His bundle or accessory pathway. Patients with WPW syndrome and atrial fibrillation almost always have inducible reciprocating tachycardias as well, which can develop into atrial fibrillation (see Fig. e37-3). In fact, interruption of the accessory pathway and elimination of AV reciprocating tachycardia usually prevent recurrence of the atrial fibrillation. Atrial fibrillation presents a potentially serious risk because of the possibility for very rapid conduction over the accessory pathway. At more rapid rates, the refractory period of the accessory pathway can shorten significantly and permit an extremely rapid ventricular response during atrial flutter or atrial fibrillation (see Fig. 37-14B). The rapid ventricular response can exceed the ability of the ventricle to follow in an organized manner; it can result in fragmented, disorganized ventricular activation and hypotension and lead to VF (see Fig. 37-22). Alternatively, a supraventricular discharge bypassing AV nodal delay can activate the ventricle during the vulnerable period of the antecedent T wave and precipitate VF. Patients who have had VF exhibit ventricular cycle lengths during atrial fibrillation in the range of 240 milliseconds or less.

Patients with preexcitation syndrome can have other causes of tachycardia, such as AV nodal reentry (sometimes with dual AV nodal curves), sinus nodal reentry, or even VT unrelated to the accessory pathway. Some accessory pathways can conduct anterogradely only; more commonly, pathways conduct retrogradely only. If the pathway conducts only anterogradely, it cannot participate in the usual form of reciprocating tachycardia (see Fig. 37-18A). It can, however, participate in antidromic tachycardia (see Fig. 37-18C), as well as conduct to the ventricle during atrial flutter or atrial fibrillation (see Fig. 37-18E). Some data suggest that the accessory pathway demonstrates automatic activity, which could conceivably be responsible for some cases of tachycardia.

FIGURE 37-19 Antidromic AV reciprocating tachycardia. The tachycardia in this example is caused by anterograde conduction over the accessory pathway (note the abnormal QRS complex of a left posterior accessory pathway) and a normal retrograde atrial activation sequence (beginning first in the HBED lead), which is caused by retrograde conduction over the AV node. The tachycardia cycle length is 390 milliseconds, with a VA interval of 300 milliseconds measured in the high right atrial lead, 260 milliseconds in the distal His lead, and 280 milliseconds in the proximal coronary sinus lead. I, II, III, and V₁ are scalar leads. DCS = distal coronary sinus lead; HBEP and HBED leads = His bundle electrogram, proximal and distal; HRA = high right atrial electrogram; MCS1 to MCS3 = midcoronary sinus leads; PCS = proximal coronary sinus; RV = right ventricular electrogram.

FIGURE 37-20 Termination of the permanent form of AV junctional reciprocating tachycardia (PJRT). In the left portion of this example, PJRT is present. The atrial activation sequence is indistinguishable from atypical AV nodal reentry and atrial tachycardia originating in the low right atrium. The response to premature stimulation identifies the tachycardia as PJRT. Premature ventricular stimulation (arrowhead) occurs at a time when the His bundle is refractory from depolarization during the tachycardia (second labeled H). Therefore premature ventricular stimulation cannot enter the AV node. Furthermore, premature ventricular stimulation does not reach the atrium. Premature ventricular stimulation, however, terminates the tachycardia. This detail can be explained only by the PVC invading and blocking in a retrogradely conducting accessory pathway. I, II, III, and V₁ are scalar electrocardiographic leads. DCS = distal coronary sinus electrogram; HBEP, HBED = His bundle electrogram, proximal and distal; HRA = high right atrial electrogram; MCS1, MCS2 = midcoronary sinus electrograms; PCS = proximal coronary sinus electrogram; RV = right ventricular electrogram.

FIGURE 37-21 Permanent form of junctional reciprocating tachycardia (PJRT) in a patient with a left-sided accessory pathway. The 12-lead ECG demonstrates a long RP interval–short PR interval tachycardia, which in contrast to the usual form of PJRT, exhibits negative P waves in leads I and aVL. The rhythm strips below (lead I) indicate that whenever a nonconducted P wave occurs, the tachycardia always terminates, only to begin again after several sinus beats. This pattern is in marked contrast to that in [Figure 37-6](#), in which the tachycardia continues despite nonconducted P waves.

FIGURE 37-22 Atrial fibrillation (AF) becoming VF. In the left portion of this panel, the ECG demonstrates AF with conduction over an accessory pathway producing a rapid ventricular response, at times in excess of 390 beats/min. In the midportion of the tracing, VF can be seen to develop. I, II, III, and V₁ are scalar electrocardiographic leads. HRA = high right atrial electrogram; RVA = right ventricular apex electrogram.

“Wide-QRS” Tachycardias

In patients with preexcitation syndrome, so-called wide-QRS tachycardias can be caused by multiple mechanisms: sinus or atrial tachycardias, AV nodal reentry, and atrial flutter or fibrillation with anterograde conduction over the accessory pathway; orthodromic reciprocating tachycardia with functional or preexisting bundle branch block; antidromic reciprocating tachycardia; reciprocating tachycardia with anterograde conduction over one accessory pathway and retrograde conduction over a second one; tachycardias using nodofascicular or atriofascicular fibers; and VT.

Clinical Features

The reported incidence of preexcitation syndrome depends in large measure on the population studied and varies from 0.1 to 3 per 1000 in apparently healthy subjects, with an average of about 1.5 per 1000. The incidence of the electrocardiographic pattern of WPW conduction in 22,500 healthy aviation personnel was 0.25%, with a prevalence of documented tachyarrhythmias of 1.8%. Left free wall

accessory pathways were most common, followed in frequency by posteroseptal, right free wall, and anteroseptal locations. WPW syndrome is found in all age groups from the fetal and neonatal periods to the elderly, as well as in identical twins. The prevalence is higher in men and decreases with age, apparently because of loss of preexcitation. Most adults with preexcitation syndrome have normal hearts, although various acquired and congenital cardiac defects have been reported, including Ebstein anomaly, mitral valve prolapse, and cardiomyopathies. Patients with Ebstein anomaly ([see Chapter 62](#)) often have multiple right-sided accessory pathways, either in the posterior septum or in the posterolateral wall, with preexcitation localized to the atrialized ventricle. They frequently have reciprocating tachycardia with a long VA interval and a right bundle branch block morphology.

The frequency of paroxysmal tachycardia apparently increases with age, from 10 per 100 patients with WPW syndrome in the 20- to 39-year-old group to 36 per 100 in patients older than 60 years.

Approximately 80% of patients with tachycardia have a reciprocating tachycardia, 15% to 30% have atrial fibrillation, and 5% have atrial flutter. VT occurs uncommonly. The anomalous complexes can mask or mimic myocardial infarction (see Chapter 51), bundle branch block, or ventricular hypertrophy, and the presence of preexcitation syndrome can suggest an associated cardiac defect. For most patients with recurrent tachycardia, the prognosis is good, but sudden death does occur rarely, with an estimated frequency of 0.1%. Risk stratification includes a stress test and EP study in selected patients (Fig. e37-4).¹²

It is highly likely that an accessory pathway is congenital, although its manifestations may be detected in later years and appear to be acquired. Relatives of patients with preexcitation, particularly those with multiple pathways, have an increased prevalence of preexcitation, thus suggesting a hereditary mode of acquisition. Some children and adults can lose their tendency for the development of tachyarrhythmias as they grow older, possibly as a result of fibrotic or other changes at the site of insertion of the accessory pathway. Pathways can lose their ability to conduct anterogradely. Tachycardia beginning in infancy can disappear but frequently recurs. Tachycardia still present after 5 years of age persists in 75% of patients, regardless of the location of the accessory pathway. Intermittent preexcitation during sinus rhythm and abrupt loss of conduction over the accessory pathway after intravenous administration of procainamide and with exercise suggest that the refractory period of the accessory pathway is long and that the patient is not at risk for a rapid ventricular rate should atrial flutter or fibrillation develop. These approaches are relatively specific but not very sensitive, with low positive predictive accuracy. Exceptions to these safeguards can occur; the only way to be certain of the accessory pathway's properties and propensity for rapid conduction is by performing an EP study.

Treatment

For patients without symptoms, risk stratification to determine the risk for sudden death as a result of rapid conduction over the accessory pathway inducing VF, though rare, may be necessary in some patients. Patients with asymptomatic intermittent ventricular preexcitation do not require further evaluation or therapy and should simply be observed.¹² Young patients (8 to 21 years of age) who have only persistent electrocardiographic abnormalities, without tachyarrhythmias or a history of palpitations, should undergo stress testing to determine whether abrupt loss of preexcitation occurs. If loss of preexcitation does not occur or is equivocal or not abrupt, an invasive EP study is recommended to further risk-stratify patients.¹² (See Fig. e37-4.) For patients with frequent episodes of symptomatic tachyarrhythmia, therapy should be initiated.

Two therapeutic options exist, catheter ablation and pharmacologic therapy. Drugs are chosen to prolong conduction time or refractoriness in the AV node, the accessory pathway, or both to prevent rapid rates from occurring. If successful, such therapy prevents maintenance of an AV reciprocating tachycardia or a rapid ventricular response to atrial flutter or atrial fibrillation. Some drugs can suppress premature complexes that precipitate the arrhythmias.

Adenosine, verapamil, propranolol, and digitalis prolong conduction time and refractoriness in the AV node. Verapamil and propranolol do not directly affect conduction in the accessory pathway, and digitalis has had variable effects. Because digitalis has been reported to shorten refractoriness in the accessory pathway and to speed the ventricular response in some patients with atrial fibrillation, it is advisable to not use digitalis as a single drug in patients with WPW syndrome who have or may have atrial flutter or atrial fibrillation. Because atrial fibrillation can develop during the reciprocating tachycardia in many patients (see Fig. e37-3), this caveat probably applies to all patients with tachycardia and WPW syndrome. Instead, drugs that prolong the refractory period in the accessory pathway should be used, such as class IA and IC drugs (see Chapter 35).

The class IC drugs, amiodarone, and sotalol can affect both the AV node and the accessory pathway. Lidocaine does not generally prolong refractoriness of the accessory pathway. Verapamil and intravenous lidocaine can increase the ventricular rate during atrial

fibrillation in patients with WPW syndrome. Intravenous verapamil can precipitate VF when given to a patient with WPW syndrome who has a rapid ventricular rate during atrial fibrillation. This effect does not seem to occur with oral verapamil. Catecholamines can expose WPW syndrome, shorten the refractory period of the accessory pathway, and reverse the effects of some antiarrhythmic drugs.

Termination of an Acute Episode

Termination of an acute episode of reciprocating tachycardia, suspected electrocardiographically from a normal QRS complex, regular R-R intervals, a rate of approximately 200 beats/minute, and a retrograde P wave in the ST segment, should be approached similarly to AV nodal reentry. After vagal maneuvers, adenosine followed by intravenous verapamil or diltiazem is the initial treatment of choice. Atrial fibrillation can occur after drug administration, particularly adenosine, along with a rapid ventricular response. An external cardioverter-defibrillator should be immediately available if necessary. For atrial flutter or fibrillation (with atrial fibrillation suspected because of an anomalous QRS complex and grossly irregular R-R intervals; see Fig. 37-14B and see Fig. e37-3), drugs must be used that prolong refractoriness in the accessory pathway, often coupled with drugs that prolong AV nodal refractoriness (e.g., procainamide, propranolol). In many patients, particularly those with a very rapid ventricular response and any signs of hemodynamic impairment, electrical cardioversion is the initial treatment of choice.

Prevention

For long-term therapy to prevent recurrence, RF catheter ablation of the accessory pathway has become the first-line therapy for most patients. For patients with frequent symptomatic arrhythmias that are not fully controlled by drugs, those who are drug intolerant, or those who do not wish to take drugs, ablation is advisable. This option should be considered early in the course of treatment of a symptomatic patient because of its high success rate, low frequency of complications, and potential cost-effectiveness. Ablation is the treatment of choice in patients with atrial fibrillation and rapid conduction over an accessory pathway. Even though transvenous catheter ablation is generally very effective, epicardial ablation through a pericardial approach or surgical interruption of the accessory pathway may be necessary in rare cases.

Drug therapy is an alternative to ablation, but it is not always possible to predict which drugs may be most effective for an individual patient. Some drugs can actually increase the frequency of episodes of reciprocating tachycardia by prolonging the duration of antegrade and not retrograde refractory periods of the accessory pathway, thereby making it easier for a PAC to block conduction anterogradely in the accessory pathway and to initiate tachycardia. Oral administration of two drugs, such as flecainide and propranolol, to decrease conduction capability in both limbs of the reentrant circuit can be beneficial. The class IC drugs amiodarone and sotalol, which prolong refractoriness in both the accessory pathway and the AV node, can be effective. Depending on the clinical situation, empiric drug trials or serial EP drug testing can be used to determine optimal drug therapy for patients with reciprocating tachycardia. For patients who have atrial fibrillation with a rapid ventricular response, induction of atrial fibrillation while the patient is receiving therapy is essential to be certain that the ventricular rate is controlled. Exercise or isoproterenol can be superimposed to be certain that the rate is controlled. Patients who have accessory pathways with very short refractory periods may be poor candidates for drug therapy because the refractory periods may be insignificantly prolonged in response to the standard agents.

Summary of Electrocardiographic Diagnosis of Supraventricular Tachycardias

Electrocardiographic clues that permit differentiation among the various SVTs are often present. P waves during tachycardia that are identical to sinus P waves and occur with a long RP interval and a short PR interval are most likely caused by sinus nodal reentry, sinus tachycardia, or an atrial tachycardia arising from the right atrium

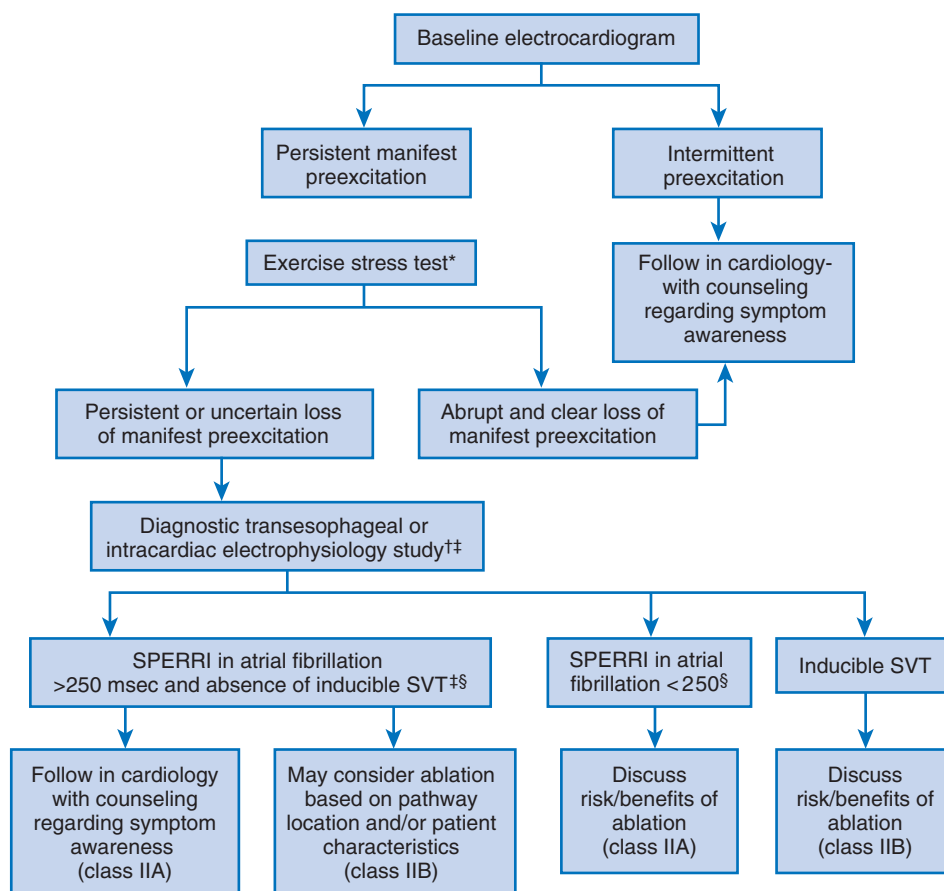

FIGURE e37-4 Baseline electrocardiogram. *Patients unable to perform an exercise stress test should undergo risk-stratification with an EP study. †Before invasive testing, patients and parents/guardians should undergo counseling to discuss the risks and benefits of proceeding with invasive studies, the risks associated with observation only, and risks related to the medication strategy. ‡Patients participating in moderate- to high-level competitive sports should be counseled with regard to the risks and benefits of ablation (class IIA) and follow the 36th Bethesda Conference guidelines. §In the absence of inducible atrial fibrillation, the shortest preexcited RR interval as determined by rapid atrial pacing is a reasonable surrogate. SPERRI = shortest preexcited RR interval. (From Cohen MI, Friedman JK, Cannon BC, et al: PACES/HRS expert consensus statement on the management of the asymptomatic young patient with a Wolff-Parkinson-White [WPW, ventricular preexcitation] electrocardiographic pattern: Developed in partnership between the Pediatric and Congenital Electrophysiology Society [PACES] and the Heart Rhythm Society [HRS]. Endorsed by the governing bodies of PACES, HRS, the American College of Cardiology Foundation [ACCF], the American Heart Association [AHA], the American Academy of Pediatrics [AAP], and the Canadian Heart Rhythm Society [CHRS]. *Heart Rhythm* 9:1006, 2012.)

near the sinus node. Retrograde (inverted in leads II, III, and aVF) P waves usually represent reentry involving the AV junction, either AV nodal reentry or reciprocating tachycardia using a paraseptal accessory pathway. Depression of the ST segment during a narrow-complex tachycardia generally signifies AV reentrant tachycardia using an accessory pathway. Tachycardia without manifest P waves is probably caused by AV nodal reentry (retrograde P waves buried in the QRS complex), whereas a tachycardia with an RP interval exceeding 90 milliseconds may be caused by an accessory pathway. AV dissociation or AV block during tachycardia excludes the participation of an AV accessory pathway and makes AV nodal reentry less likely. Multiple tachycardias can occur at different times in the same patient. QRS alternans, thought to be a feature of AV reciprocating tachycardia, is more likely a rapid rate–related phenomenon independent of the tachycardia mechanism. RP-PR relationships (Table 37-5) help differentiate SVTs. QRS voltage can increase during SVT.

VENTRICULAR RHYTHM DISTURBANCES

Premature Ventricular Complexes Electrocardiographic Recognition

A PVC is characterized by the premature occurrence of a QRS complex that is abnormal in shape and has a duration usually exceeding the dominant QRS complex, generally longer than 120 milliseconds. The T wave is usually large and opposite in direction to the major deflection of the QRS. The QRS complex is not preceded by a premature P wave but can be preceded by a nonconducted sinus P wave occurring at its expected time. Diagnosis of a PVC can never be made with unequivocal certainty from the scalar ECG because a supraventricular beat or rhythm can mimic the manifestations of ventricular arrhythmia (Fig. 37-23). Retrograde transmission to the atria from the PVC occurs fairly frequently but is often obscured by the distorted QRS complex and T wave. If the retrograde impulse discharges and resets the sinus node prematurely, it produces a pause that is not fully compensatory. More commonly, the sinus node and atria are not discharged prematurely by the retrograde impulse because interference of impulses frequently occurs at the AV junction in the form of a collision between the anterograde impulse conducted from the sinus node and the retrograde impulse conducted from the PVC. Therefore, a fully compensatory pause usually follows a PVC—the R-R interval produced by the two sinus-initiated QRS complexes on either side of the PVC equals twice the normally conducted R-R interval. The PVC may not produce any pause and can therefore be interpolated (see Fig. 37-23E).

Interference within the ventricle can result in ventricular fusion beats caused by simultaneous activation of the ventricle by two foci, one from the supraventricular impulse and the other from the PVC. On occasion, a fusion beat can be narrower than the dominant sinus beat, such as when a right bundle branch block pattern of a PVC arising in the left ventricle fuses with the sinus-initiated left bundle branch block complex conducting through the AV junction or when a sinus beat with a right bundle branch block pattern fuses with an RV paced beat with a left bundle branch block pattern. Narrow PVCs have also been explained as originating at a point equidistant from

each ventricle in the ventricular septum and arising high in the fascicular system. Whether a compensatory or noncompensatory pause, retrograde atrial excitation, an interpolated complex, a fusion complex, or an echo beat occurs (see Fig. 37-23D) is merely a function of how the AV junction conducts and the timing of the events taking place.

The term *bigeminy* refers to pairs of complexes and indicates a normal and premature complex, *trigeminy* indicates a premature complex that follows two normal beats, a premature complex that follows three normal beats is called *quadrigeminy*, and so on. Two successive PVCs are known as a pair or a couplet, whereas three successive PVCs are called a triplet. Arbitrarily, three or more successive PVCs are termed *ventricular tachycardia*. PVCs can have different contours and are often called multifocal (Fig. 37-24). More properly, they should be called multiform, polymorphic, or pleomorphic because it is not known whether multiple foci are discharging or whether conduction of the impulse originating from one site is merely changing.

PVCs can exhibit fixed or variable coupling; that is, the interval between the normal QRS complex and the PVC can be relatively stable or variable. Fixed coupling can be caused by reentry, triggered activity (see Chapter 33), or other mechanisms. Variable coupling can be caused by parasystole, changing conduction in a reentrant circuit, or changing discharge rates of triggered activity. Usually, it is difficult to determine the precise mechanism responsible for the PVC on the basis of constant or variable coupling intervals.

Clinical Features

The prevalence of premature complexes increases with age, male sex, and hypokalemia. Symptoms of palpitations or discomfort in the neck or chest can result because of the greater than normal contractile force of the postextrasystolic beat or the feeling that the heart has stopped during the long pause after the premature complex. Long runs of frequent PVCs in patients with heart disease can produce angina, hypotension, or heart failure. Frequent interpolated PVCs actually represent a doubling of the heart rate and can compromise the patient's hemodynamic status. In some patients, frequent PVCs alone can cause heart failure, which is reversed when the PVC site is ablated. Activity that increases the heart rate can decrease the patient's awareness of the premature systoles or reduce their number. Exercise can increase the number of premature complexes in some patients. Premature systoles can be very uncomfortable in patients with aortic regurgitation because of their large stroke volume. Sleep is usually associated with a decrease in the frequency of ventricular arrhythmias, but some patients can experience an increase.

PVCs occur in association with various stimuli and can be produced by direct mechanical, electrical, and chemical stimulation of the myocardium. Frequently, they are noted in patients with left ventricular (LV) false tendons, during infection, in ischemic or inflamed myocardium, and during hypoxia, anesthesia, or surgery. They can be provoked by various medications, electrolyte imbalance, tension states, myocardial stretch, and excessive use of tobacco, caffeine, or alcohol. Both central and peripheral autonomic stimulation has profound effects on the heart rate and can produce or suppress premature complexes.

Physical examination reveals a premature beat followed by a long pause. A fully compensatory pause can be distinguished from one that is not fully compensatory in that the former does not change the timing of the basic rhythm. The premature beat is frequently accompanied by a decrease in intensity of the heart sounds, often with auscultation of just the first heart sound, which can be sharp and snapping, and a decreased or absent peripheral (e.g., radial) pulse. The relationship of atrial to ventricular systole determines the presence of normal *a* waves or giant *a* waves in the jugular venous pulse, and the length of the PR interval determines the intensity of the first heart sound. The second heart sound can be split abnormally, depending on the origin of the ventricular complex.

The importance of PVCs depends on the clinical setting. In the absence of underlying heart disease, the presence of PVCs usually has no impact on longevity or limitation of activity; antiarrhythmic

FIGURE 37-23 PVCs. **A** to **D** were recorded in the same patient. **A**, A late PVC results in a compensatory pause. **B**, A slower sinus rate and a slightly earlier PVC result in retrograde atrial excitation (P'). The sinus node is reset, followed by a noncompensatory pause. Before the sinus-initiated P wave that follows the retrograde P wave can conduct the impulse to the ventricle, ventricular escape (E) occurs. **C**, Events are similar to those in **B** except that a ventricular fusion beat (F) results after the PVC because of a slightly faster sinus rate. **D**, The impulse propagating retrogradely to the atrium reverses its direction after a delay and returns to reexcite the ventricles (R) and produce a ventricular echo. **E**, An interpolated PVC is followed by a slightly prolonged PR interval of the sinus-initiated beat. The lead II ECG is shown. Red circles indicate the origin of the PVCs.

FIGURE 37-24 Multiform PVCs. The normally conducted QRS complexes exhibit a left bundle branch block contour (arrowhead) and are followed by PVCs with three different morphologies.

drugs are not indicated. Patients should be reassured if they are symptomatic. Frequent PVCs can lead to LV dysfunction over time. Features predicting the development of PVC-induced cardiomyopathy are a PVC burden greater than 24% (e.g., 24% of all beats during 24-hour Holter monitoring are PVCs), very wide-QRS PVCs, or PVCs of epicardial origin.¹³⁻¹⁵ Ablation generally resolves the cardiomyopathy, although the LV dysfunction may not resolve completely, depending on the duration and severity of the PVC-induced cardiomyopathy.

In patients suffering from acute myocardial infarction, PVCs once considered to presage the onset of VF, such as those occurring close to the preceding T wave, more than five or six per minute, bigeminal or multiform complexes, or those occurring in salvos of two or three or more, do not occur in approximately 50% of patients in whom VF develops, and VF does not develop in about 50% of patients who have these PVCs. Thus, these PVCs are not particularly sensitive or specific in determining in whom VF will develop in this setting. The presence of one to 10 or more ventricular extrasystoles per hour can identify patients at increased risk for VT or sudden cardiac death after myocardial infarction, but this is similarly nonspecific.

Management

In most patients, PVCs (occurring as single PVCs, bigeminy, or trigeminy but excluding nonsustained VT; see later) do not need to be treated, particularly if the patient does not have an acute coronary syndrome, and treatment is usually dictated by the presence of symptoms attributable to the PVCs. PVCs accompanying slow ventricular rates can be abolished by increasing the basic rate with atropine or isoproterenol or by pacing, whereas slowing of the heart rate in some patients with sinus tachycardia can eradicate PVCs. In hospitalized patients, intravenous lidocaine (see Chapter 35) is generally the initial treatment of choice to suppress PVCs but is rarely indicated. Frequent PVCs, even in the setting of acute myocardial infarction, need not be treated unless they directly contribute to hemodynamic compromise, which is very rare. If maximum dosages of lidocaine are unsuccessful, intravenous procainamide can be tried. Propranolol is suggested if other drugs have been unsuccessful. Intravenous magnesium may be useful. In most patients, PVCs need not be treated, and reassurance that they are benign in those without structural heart disease is often sufficient for most patients. If treatment is warranted (dictated by symptoms), various class I, II, and III drugs or ablation can be useful. Beta blockers are often the first line of therapy. If they are ineffective, class IC drugs appear to be particularly successful in suppressing PVCs, but flecainide and moricizine have been shown to increase mortality in patients treated after myocardial infarction and thus should be reserved for those without coronary artery disease or LV dysfunction. Amiodarone can be effective, but because of its side effects, it should be reserved for highly symptomatic patients and those with structural heart disease. For patients with significant symptoms, particularly those with reduced cardiac function, RF ablation of the PVC focus can be effective and improve cardiac performance. Low levels of serum potassium and magnesium are associated with higher prevalence rates of ventricular arrhythmias.

Accelerated Idioventricular Rhythm

Electrocardiographic Recognition. The ventricular rate, commonly between 60 and 110 beats/minute, usually hovers within 10 beats of the sinus rate, so control of the cardiac rhythm shifts between these two competing pacemaker sites. Consequently, fusion beats often occur at the onset and termination of the arrhythmia as the pacemakers vie for control of ventricular depolarization (Fig. 37-25). Because of the slow rate, capture beats are common. The onset of this arrhythmia is generally gradual (nonparoxysmal) and occurs when the rate of the VT exceeds the sinus rate as a result of sinus slowing or SA or AV block. The ectopic mechanism can also begin after a PVC, or the ectopic ventricular focus can simply accelerate sufficiently to overtake the sinus rhythm. The slow rate and nonparoxysmal onset avoid the problems initiated by excitation during the vulnerable period, and consequently, precipitation of more rapid ventricular arrhythmias is rarely seen. Termination of the rhythm generally occurs gradually as the dominant sinus rhythm accelerates or as the ectopic

FIGURE 37-25 Accelerated idioventricular rhythm. In this continuous monitor lead recording, an accelerated idioventricular rhythm competes with the sinus rhythm. Wide QRS complexes at a rate of 110 beats/min fuse (F) with the sinus rhythm, which takes control briefly, generates the narrow QRS complexes, and then yields once again to the accelerated idioventricular rhythm as the P waves move “in and out” of the QRS complex. This example of isorhythmic AV dissociation may be caused by hemodynamic modulation of the sinus rate via the autonomic nervous system.

ventricular rhythm decelerates. The ventricular rhythm can be regular or irregular and can occasionally show sudden doubling, which suggests the presence of an exit block. Many characteristics incriminate enhanced automaticity as the responsible mechanism.

The arrhythmia occurs as a rule in patients who have heart disease, such as those with acute myocardial infarction or digitalis toxicity. It is transient and intermittent, with episodes lasting a few seconds to a minute, and does not appear to seriously affect the patient's clinical course or the prognosis. It commonly occurs at the moment of reperfusion of a previously occluded coronary artery and can be found during resuscitation.

Management. Suppressive therapy is rarely necessary because the ventricular rate is generally less than 100 beats/minute, but such therapy may be considered when AV dissociation results in loss of sequential AV contraction, an accelerated idioventricular rhythm occurs together with a more rapid VT, an accelerated idioventricular rhythm begins with a PVC discharging in the vulnerable period of the preceding T wave, the ventricular rate is too rapid and produces symptoms, or VF develops as a result of the accelerated idioventricular rhythm. This last event appears to be fairly rare. Therapy, when indicated, should be as noted earlier for VT. Frequently, simply increasing the sinus rate with atropine or atrial pacing suppresses the accelerated idioventricular rhythm.

Ventricular Tachycardia

VT arises distal to the bifurcation of the His bundle in the specialized conduction system, ventricular muscle, or combinations of both types of tissue. Mechanisms include disorders of impulse formation (enhanced automaticity or triggered activity) and conduction (reentry), considered earlier (see Chapter 33). In general, the specific type, prognosis, and management of VT depend on whether underlying structural heart disease is present. With the exception of patients with inherited VT-sudden cardiac death syndromes (see Chapter 32), if structural heart disease is absent, the prognosis in patients with VT and PVCs is generally very good,^{16,17} whereas in those with structural heart disease, the subsequent risk for sudden cardiac death is increased.

Electrocardiographic Recognition

The electrocardiographic diagnosis of VT is suggested by the occurrence of a series of three or more consecutive, abnormally shaped PVCs whose duration exceeds 120 milliseconds, with the ST-T vector pointing opposite the major QRS deflection. The R-R interval can be exceedingly regular or can vary. Patients can have VTs with multiple morphologies originating at the same or closely adjacent sites, probably with different exit paths. Others have multiple sites of origin. Atrial activity can be independent of ventricular activity, or the atria can be depolarized by the ventricles retrogradely (VA association). Depending on the particular type of VT, rates range from 70 to 250 beats/minute, and the onset can be paroxysmal (sudden) or nonparoxysmal. QRS contours during the VT can be unchanging (uniform,

FIGURE 37-26 Initiation and termination of VT by means of programmed ventricular stimulation. The last two ventricular paced beats at a cycle length of 600 milliseconds are shown in **A**. A premature stimulus (S_2) at an S_1 - S_2 interval of 260 milliseconds and another premature stimulus (S_3) at a cycle length of 210 milliseconds initiate sustained monomorphic VT at a cycle length of 300 milliseconds. **B**, Two premature ventricular stimuli (S_1 - S_2) create an unstable VT that persists for several beats at a shorter cycle length (230 msec) and then terminates, followed by sinus rhythm. HBE = His bundle electrogram; RV = right ventricle.

monomorphic) or can vary randomly (multiform, polymorphic, or pleomorphic) in a more or less repetitive manner (torsades de pointes), in alternate complexes (bidirectional VT), or in a stable but changing contour (i.e., right bundle branch contour changing to a left bundle branch contour). VT can be sustained, defined arbitrarily as lasting longer than 30 seconds or requiring termination because of hemodynamic collapse, or nonsustained, when it stops spontaneously in less than 30 seconds. Most commonly, very premature stimulation is required to initiate VT electrically, whereas late-coupled ventricular complexes usually initiate its spontaneous onset (Fig. 37-26).

Electrocardiographic distinction between SVT with aberration and VT can be difficult at times because features of both arrhythmias

TABLE 37-6 Major Features in the Differential Diagnosis of Wide-QRS Beats Versus Tachycardia

SUPPORTS SVT	SUPPORTS VT
Slowing or termination by vagal tone	Fusion beats
Onset with premature P wave	Capture beats
RP interval ≤ 100 msec	AV dissociation
P and QRS rate and rhythm linked to suggest that ventricular activation depends on atrial discharge, e.g., 2:1 AV block rS' V_1	P and QRS rate and rhythm linked to suggest that atrial activation depends on ventricular discharge, e.g., 2:1 VA block
Long-short cycle sequence	"Compensatory" pause
	Left-axis deviation; QRS duration >140 msec
	Specific QRS contours (see text)

overlap, and under certain circumstances SVT can mimic the criteria established for VT.⁴ Ventricular complexes with an abnormal and prolonged configuration indicate only that conduction through the ventricle is abnormal, and such complexes can occur in supraventricular rhythms as a result of preexisting bundle branch block, aberrant conduction during incomplete recovery of repolarization, conduction over accessory pathways, and several other conditions. These complexes do not necessarily indicate the origin of impulse formation or the reason for the abnormal conduction. Conversely, ectopic beats originating in the ventricle can uncommonly have a fairly normal duration and shape. However, VT is the most common cause of tachycardia with a wide QRS complex. A past history of myocardial infarction makes the diagnosis even more likely.

During the course of a tachycardia characterized by wide, abnormal QRS complexes, the presence of fusion beats and capture beats provides maximum support for the diagnosis of VT but occurs relatively infrequently (Fig. 37-27 and Table 37-6). Fusion beats indicate activation of the ventricle from two different foci, with the implication that one of the foci had a ventricular origin. Capture of the ventricle by the supraventricular rhythm with a normal configuration of the captured QRS complex at an interval shorter than the tachycardia in question indicates that the impulse has a supraventricular origin and thus excludes a supraventricular origin of the tachycardia. AV dissociation has long been considered a hallmark of VT. However, retrograde VA conduction to the atria from ventricular beats occurs in at least 25% of patients, and therefore VT may not exhibit AV dissociation. AV dissociation can occur uncommonly during SVTs. Even if a P wave appears to be related to each QRS complex, it is at times difficult to determine whether the P wave is conducted anterogradely to the next QRS complex (i.e., SVT with aberrancy and a long PR interval) or retrogradely from the preceding QRS complex (i.e., a VT). As a general rule, however, AV dissociation during tachycardia with a wide QRS complex is strong presumptive evidence that the tachycardia is of ventricular origin.

FIGURE 37-27 Fusion and capture beats during VT. The QRS complex is prolonged, and the R-R interval is regular except for occasional capture beats (C) that have a normal contour and are slightly premature. Complexes intermediate in contour represent fusion beats (F). Thus, even though atrial activity is not clearly apparent, AV dissociation is present during VT and produces intermittent capture and fusion beats.

Differentiation Between Ventricular and Supraventricular Tachycardia

Although fusion and capture beats and AV dissociation provide the strongest electrocardiographic evidence for differentiation of VT from SVT with aberrant conduction, these features are not always present. Therefore, other clues from the ECG may be required to help in such differentiation. Features characterizing supraventricular arrhythmia with aberrancy include the following: (1) consistent onset of the tachycardia with a premature P wave; (2) very short RP interval (0.1 second), which often requires an esophageal recording to visualize the P waves; (3) QRS configuration the same as that occurring from known supraventricular conduction at similar rates; (4) P wave and QRS rate and rhythm linked to suggest that ventricular activation depends on atrial

discharge (e.g., an AV Wenckebach block); and (5) slowing or termination of the tachycardia by vagal maneuvers.

Analysis of specific QRS contours can also be helpful in the diagnosis of VT and localization of its site of origin. For example, QRS contours suggesting VT include left-axis deviation in the frontal plane and a QRS duration exceeding 140 milliseconds with normal duration during sinus rhythm. In precordial leads with an RS pattern, the duration of the onset of the R to the nadir of the S exceeding 100 milliseconds suggests VT as the diagnosis. During VT with a right bundle branch block appearance, (1) the QRS complex is monophasic or biphasic in V_1 , with an initial deflection different from that of the sinus-initiated QRS complex; (2) the amplitude of the R wave in V_1 exceeds that of R' ; and (3) a small R and large S wave or a QS pattern in V_6 may be present. With a VT having a left bundle branch block contour, (1) the axis can be rightward, with negative deflections deeper in V_1 than in V_6 ; (2) a broad prolonged (>40 msec) R wave can be noted in V_1 ; and (3) a small Q–large R wave or QS pattern in V_6 can exist. A QRS complex that is similar in V_1 through V_6 , either all negative or all positive, favors a ventricular origin, as does the presence of a 2:1 VA block. (An upright QRS complex in V_1 through V_6

can also occur as a result of conduction over a left-sided accessory pathway.) Supraventricular beats with aberration often have a triphasic pattern in V_1 , an initial vector of the abnormal complex similar to that of the normally conducted beats, and a wide QRS complex that terminates a short cycle length after a long cycle (long-short cycle sequence). During atrial fibrillation, fixed coupling, short coupling intervals, a long pause after the abnormal beat, and runs of bigeminy rather than a consecutive series of abnormal complexes all favor a ventricular origin of the premature complex rather than a supraventricular origin with aberration. A grossly irregular, wide-QRS tachycardia with ventricular rates exceeding 200 beats/minute should raise the question of atrial fibrillation with conduction over an accessory pathway (see Fig. 37-22). In the presence of a preexisting bundle branch block, a wide-QRS tachycardia with a contour different from the contour during sinus rhythm is most likely a VT. On the basis of these criteria, several algorithms to distinguish VT from SVT with aberrancy have been suggested, one of which is shown in Figure 37-28 and Table 37-7. Exceptions exist to all the aforementioned criteria, especially in patients with preexisting conduction disturbances or preexcitation syndrome; when in doubt, one must rely on

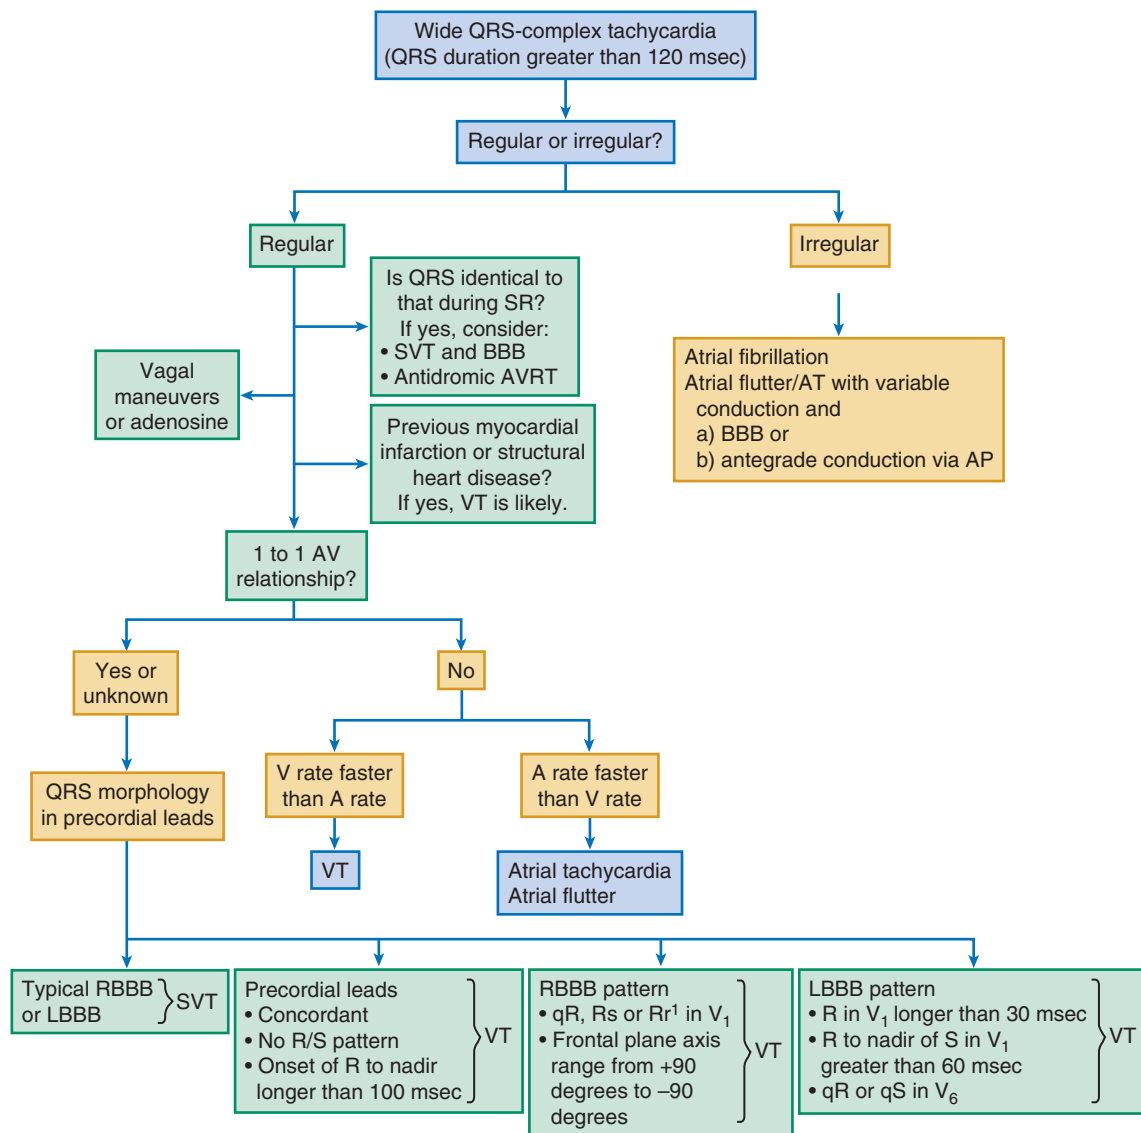

FIGURE 37-28 Algorithm for diagnosis of wide-QRS tachycardia. AP = accessory pathway; AT = atrial tachycardia; AVRT = AV reentrant tachycardia; LBBB = left bundle branch block; RBBB = right bundle branch block. (From Blomstrom-Lundqvist C, Scheinman MM, Aliot EM, et al: ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias—executive summary: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop Guidelines for the Management of Patients With Supraventricular Arrhythmias]. *Circulation* 108:1871, 2003.)

TABLE 37-7 Stepwise Criteria Favoring Ventricular Tachycardia in Patients with Wide-Complex Tachycardias Using Different Algorithms

ACC/AHA/ESC ALGORITHM	KINDWALL CRITERIA	WELLENS CRITERIA	BRUGADA CRITERIA	MILLER CRITERIA
See Figure 37-28	R >30 msec in V ₁ or V ₂ → VT	AV dissociation → VT	Absence of RS complex in all precordial leads → VT	Initial R wave in aVR → VT
	Any Q in V ₆ → VT	QRS width >140 msec → VT	Longest R/S interval >100 msec in any precordial lead → VT	aVR with initial r or q >40 msec in duration → VT
	>60 msec to S wave nadir in V ₁ or V ₂ → VT	Left axis deviation >−30° → VT	AV dissociation → VT	aVR with a notch on the descending limb of a negative-onset and predominantly negative QRS in aVR → VT
	Notched downstroke S wave in V ₁ or V ₂ → VT	If RBBB morphology, monophasic or biphasic QRS in V ₁ → SVT or R-to-S ratio of <1 in V ₆ → VT	If RBBB morphology, monophasic R or qR in V ₁ → VT R taller than R' → VT rS in V ₆ → VT	In aVR, mV of initial 40 msec divided by terminal 40 msec (v/v _t ≤1) → VT
		If LBBB morphology, S in V ₁ -V ₂ → VT	If LBBB morphology, initial R >40 msec in duration → VT Slurred or notched S in V ₁ or V ₂ → VT Beginning Q or QS in V ₆ → VT

LBBB = left bundle branch block; RBBB = right bundle branch block.

sound clinical judgment and consider the ECG as only one of several helpful ancillary tests. Vagal maneuvers can terminate RV outflow tract VTs.

The VT origin or exit site can often be determined on the surface ECG. VTs from the left ventricular free wall typically exhibit a right bundle branch block contour, whereas those from the right ventricle or septum have a left bundle branch block contour (Fig. 37-29A). Septal VTs typically have narrower QRS complexes than free wall VTs do. Apical VTs exhibit negative precordial lead concordance, whereas more basal sites typically have positive concordance. VTs from the posterior (inferior) left or right ventricle often have predominately negative QRS complexes in leads II, III, and aVF (Fig. 37-29B), whereas outflow tract VTs frequently exhibit predominately positive QRS complexes in these leads. Epicardial VTs have a delayed intrinsicoid (initial) deflection that slurs the early portion of the QRS complex; an intrinsicoid deflection exceeding 55% of the QRS duration is likely to be epicardial (see Fig. 37-29B).

Electrophysiologic Features

VT can be distinguished electrophysiologically by a short or negative H-V interval (i.e., H begins after the onset of ventricular depolarization) because of retrograde activation from the ventricles (see Chapters 33 and 34). His bundle deflections are usually obscured by simultaneous ventricular septal depolarization or inadequate catheter position. The latter must be determined during supraventricular rhythm before the onset or after the termination of VT (see Fig. 37-26). His bundle deflections dissociated from more rapid ventricular activation are diagnostic of VT, with rare exceptions.

Successful electrical induction of VT by premature ventricular stimulation (see Fig. 37-26) depends on the characteristics of the VT and the anatomic substrate. Patients with sustained, hemodynamically stable VT and VT secondary to chronic coronary artery disease have monomorphic VT induced more frequently (90%) than do patients with nonsustained VT, VT from non-coronary-related causes or acute ischemia, and cardiac arrest (40% to 75%). In general, it is

more difficult to induce VT with late premature ventricular stimuli than with early premature stimuli, during sinus rhythm than during ventricular pacing, with one premature stimulus than with two or three, and in normal hearts. The specificity of VT induction using more than two premature ventricular stimuli begins to decrease, whereas the sensitivity increases; nonsustained polymorphic VT or VF can be induced in patients who have no history of VT. On occasion, VT can be initiated only from the left ventricle or from specific sites in the right ventricle when they are closer to the reentrant circuit. Multiple premature stimuli can reduce the need for LV stimulation. Drugs such as isoproterenol can facilitate the induction of VT. Coughing during VT that causes hypotension can help maintain blood pressure.

Termination by pacing depends on the mechanism (reentrant VT can be pace-terminated), rate of the VT, and the site of pacing. Slower VTs are terminated more easily and with fewer stimuli. An increasing number of stimuli are required to terminate more rapid VTs, which increases the risks associated with pacing-induced VT acceleration.

Clinical Features

Symptoms during VT depend on the ventricular rate, duration of the tachycardia, and the presence and extent of the underlying heart disease and peripheral vascular disease. VT can occur in several forms: short, asymptomatic, nonsustained episodes; sustained, hemodynamically stable events (generally occurring at slower rates or in otherwise normal hearts); or unstable runs, often resulting in hemodynamic collapse and degenerating into VF. Nonsustained VTs initially can become sustained. Physical findings depend in part on the P-to-QRS relationship. If atrial activity is dissociated from the ventricular contractions, the findings of AV dissociation are present. If the atria are captured retrogradely, regularly occurring cannon *a* waves appear when atrial and ventricular contractions occur simultaneously, and signs of AV dissociation are absent.

Most patients treated for symptomatic recurrent VT have ischemic heart disease. The next largest group has cardiomyopathy (both

FIGURE 37-29 **A**, VT in a patient with a previous myocardial infarction. The VT exit is in the left ventricular septum (left bundle branch block morphology), inferiorly (QS in II, III, and aVF) close to the apex (QS in V₆). **B**, Epicardial ventricular tachycardia in a patient with Chagas disease. The VT has shortest intrinsicoid deflection, greater than 55% of the QRS in the precordium, and is therefore of epicardial origin. Because it has right bundle branch block morphology in V₁ and QS in leads II, III, and aVF, the origin is in the inferior left ventricle.

congestive and hypertrophic; [see Chapters 65 and 66](#)), with lesser percentages divided among those with primary electrical disease such as inherited ion channel abnormalities ([see Chapter 32](#)), idiopathic VT, congenital heart disease ([see Chapter 62](#)), and miscellaneous causes. LV hypertrophy can lead to ventricular arrhythmias. Coronary artery spasm can cause transient myocardial ischemia with severe ventricular arrhythmias in some patients, during ischemia as well as during the apparent reperfusion period ([see Chapter 52](#)). Complex ventricular arrhythmias can occur after coronary artery bypass grafting. In patients resuscitated from sudden cardiac death ([see Chapter 39](#)), many have coronary artery disease or cardiomyopathy. When VT occurs in an ambulatory patient, it is uncommonly induced by R-on-T PVCs. Patients with sustained VT are more likely to have a reduced ejection fraction, slowed intraventricular conduction and electrographic abnormalities (e.g., wide QRS), LV aneurysm, and previous myocardial infarction. In patients with coronary artery disease, sustained VT displays a circadian variation, with the peak frequency occurring in the morning.

Many approaches have been used to assess prognosis in patients with ventricular arrhythmias, although none have sufficient positive

or negative predictive value ([see Chapter 34](#)). Inducibility of VT during an EP study, reduced LV function, spontaneous ventricular arrhythmias, late potentials on a signal-averaged ECG, QT-interval dispersion, T wave alternans, prolonged QRS duration, heart rate turbulence, decreased heart rate variability, and reduced baroreceptor sensitivity all carry increased risk for total and sudden death. Currently, however, no technique reliably predicts outcome better than does assessment of LV function. LV function and inducibility of VT during EP study are the two strongest predictors of a poor outcome. In general, the prognosis for patients with idiopathic VT (see later) in the absence of structural heart disease is good, and less aggressive treatment is warranted than for patients with structural heart disease. Patients with inherited arrhythmia syndromes are an exception to this statement ([see Chapter 32](#)).

Management

The dramatic changes in the management of VT and aborted sudden death during the past two decades have been fueled by several large clinical trials ([Table 37-8](#)) and development of the ICD. Management decisions can be stratified into those involved in acute management

**TABLE 37-8 Clinical Trials on the Treatment of Ventricular Tachycardia and Prevention of Cardiac Arrest**

STUDY	PATIENT INCLUSION	ENDPOINTS	TREATMENT ARMS	KEY RESULTS
Primary Prevention Studies				
BHAT ^a	Post-MI	Total mortality Sudden cardiac death	Propranolol Placebo	Total mortality, sudden cardiac death reduced in the treatment arm
CAST ^{b,c}	Post-MI ≥6 PVCs/hr LVEF ≤40%	Arrhythmic death	Flecainide Encainide Morizine Placebo	Arrhythmic death increased in all treatment arms
SWORD ^d	Post-MI LVEF <40% or Remote MI NYHA class II-III	Total mortality	d-Sotalol Placebo	Increased mortality in the treatment arm
EMIAT ^e	Post-MI LVEF <40%	Total mortality Arrhythmic death	Amiodarone Placebo	Amiodarone reduced arrhythmic death but not total mortality
CAMIAT ^f	Post-MI ≥10 PVCs/hr or NSVT	Arrhythmic death Total mortality	Amiodarone Placebo	Amiodarone reduced arrhythmic death but not total mortality
GESICA ^g	CHF LVEF ≤35%	Total mortality	Amiodarone Best therapy	Amiodarone reduced mortality; patients with NSVT had higher mortality
CHF-STAT ^h	CHF LVEF ≤40% ≥10 PVCs/hr (asymptomatic)	Total mortality	Amiodarone Placebo	No effect on ischemic cardiomyopathy but trend toward reduced mortality in nonischemic cardiomyopathy
CABG-PATCH ⁱ	CAD undergoing CABG LVEF <36% Positive SAECG	Total mortality	CABG CABG + ICD	No difference in total mortality
MADIT ^j	Post-MI NSVT LVEF ≤35% NYHA class I-III Inducible VT not suppressed by procainamide	Total mortality	ICD Antiarrhythmic drug (80% amiodarone)	ICD reduced mortality
MUST ^k	Post-MI LVEF <40% NSVT	Arrhythmic death or cardiac arrest	ICD in nonsuppressible group Antiarrhythmic drug in suppressible group No therapy	Improved survival in ICD group; no difference between no therapy and antiarrhythmic group
MADIT II ^l	Post-MI EF ≤30% >10 PVCs/hr or couplets	Total mortality	ICD No ICD	Improved survival in ICD arm
DINAMIT ^m	Immediately post-MI EF ≤35%	Total mortality Arrhythmic mortality	ICD No ICD	No improvement in survival with ICD
IRIS ⁿ	Immediately post-MI EF ≤40%	Total mortality	ICD No ICD	No improvement in survival with ICD
COMPANION ^o	Ischemic or nonischemic CM NYHA class III-IV QRS ≥120 msec	Total mortality	Medical therapy PM-CRT ICD-CRT	Improved survival in ICD-CRT group > PM-CRT > medical therapy
DEFINITE ^p	Nonischemic CM EF ≤36% PVCs or NSVT	Total mortality Arrhythmic mortality	ICD No ICD	Improved survival in the ICD arm
SCD-HeFT ^q	CHF LVEF ≤35% NYHA class II-III	Total mortality Arrhythmic mortality Cost Quality of life	ICD Amiodarone Placebo	Improved survival with ICD; no effect of amiodarone on survival

(or termination) and those involved in long-term therapy (or prevention of recurrence or sudden death; [see Chapters 35 and 39](#)).

Acute Management of Sustained Ventricular Tachycardia

VT that does not cause hemodynamic decompensation can be treated medically to achieve acute termination via the intravenous administration of amiodarone, lidocaine, or procainamide, followed by an infusion of the successful drug. Lidocaine is often ineffective; amiodarone and procainamide appear to be superior. In patients in

whom procainamide is ineffective or may be problematic (severe heart failure, renal failure), intravenous amiodarone is frequently effective. In general, an initial amiodarone loading dose of 15 mg/min is given during a 10-minute period. This dose is followed by an infusion of 1 mg/min for 6 hours and then a maintenance dose of 0.5 mg/min for the remaining 18 hours and for the next several days, as necessary. If the VT does not terminate or if it recurs, a repeated loading dose can be given. Rarely, sinus bradycardia or AV block can be seen with intravenous amiodarone. The hypotension associated with intravenous amiodarone, caused largely by the

diluent used in earlier formulations, does not seem to be a frequent problem and is usually related to the rate of infusion.

If the arrhythmia does not respond to medical therapy, electrical DC cardioversion can be used. VT that precipitates hypotension, shock, angina, congestive heart failure, or symptoms of cerebral hypoperfusion should be treated promptly with DC cardioversion (see Chapters 35 and 39). Very low energies can terminate VT, beginning with a synchronized shock of 10 to 50 J. After conversion of the arrhythmia to a normal rhythm, it is essential to institute measures to prevent recurrence.

When a defibrillator is not readily available, striking the patient's chest can infrequently terminate the VT. However, chest stimulation at the time of the vulnerable period during the arrhythmia can accelerate the VT or possibly provoke VF.

In some cases, such as VT associated with a remote myocardial infarction (which is caused by reentry), ventricular pacing via a pacing catheter inserted into the right ventricle or transcutaneously at rates faster than the tachycardia can terminate the tachycardia. This procedure incurs the risk of accelerating the VT to ventricular flutter or VF. In patients with recurrent VT, overdrive ventricular pacing can be used to prevent recurrences. Intermittent VT, interrupted by several supraventricular beats, is generally best treated pharmacologically.

A search for reversible conditions contributing to the initiation and maintenance of VT should be made and the conditions corrected, if possible. For example, VT related to ischemia, hypotension, or hypokalemia can at times be terminated by antianginal treatment, vasopressors, or potassium, respectively. Correction of heart failure can reduce the frequency of ventricular arrhythmias. Slow ventricular rates caused by sinus bradycardia or AV block can permit the occurrence of PVCs and ventricular tachyarrhythmias, which is corrected by transvenous pacing. Rarely, SVT can initiate ventricular tachyarrhythmias and should be prevented if this is the observed mechanism of VT initiation.

Long-Term Therapy for Prevention of Recurrences

Because the goal of long-term therapy is to prevent sudden cardiac death and recurrence of symptomatic VT, asymptomatic nonsustained ventricular arrhythmias in low-risk populations (i.e., preserved LV function) often need not be treated. In patients with symptomatic nonsustained tachycardia, beta blockers are frequently effective in preventing recurrences. In patients refractory to beta blockers, class IC agents, sotalol, or amiodarone can be effective. However, class IC agents should be avoided in patients with structural heart disease, especially those with coronary artery disease, because of the increased mortality associated with these drugs secondary to their proarrhythmic effects. Sotalol should be used cautiously because of its potential for prolonging the QT interval and producing torsades de pointes. Patients with nonsustained VT after myocardial infarction and poor LV function are at significant risk for sudden death. The major multicenter, randomized ICD trials are summarized in Table 37-8.

For secondary prevention of sustained VT or cardiac arrest (see Table 37-8 and Chapters 35 and 39) in patients with structural heart disease, it is now clear from several clinical trials that (1) class I antiarrhythmic drugs produce a worse outcome than do class III antiarrhythmic drugs, (2) empiric amiodarone results in better survival than does EP-guided antiarrhythmic drugs, and (3) ICDs provide better survival than amiodarone does, particularly in patients with an LV ejection fraction of less than 0.35. Therefore, in patients who have survived cardiac arrest or who have sustained VT resulting in hemodynamic compromise and poor LV function, an ICD is the treatment of choice. In patients who refuse an ICD, empiric amiodarone may be the next best therapy, although no reduction in mortality was found in SCD-HeFT. The optimal therapy for patients with coronary disease who have preserved LV function with *sustained* VT is not currently known. Empiric amiodarone appears to be the safest therapy, although Holter-guided sotalol has been advocated. Some patients who receive ICDs experience frequent shocks because of recurrent VT. In these patients, concomitant therapy with

amiodarone or ablation may be required to reduce the frequency of VT or to slow the rate of the VT so that it can be pace-terminated. Other drugs, such as sotalol, procainamide, mexiletine, and flecainide, may be required if amiodarone is not effective. On occasion, a combination of drugs can be effective when a single drug is not. Ablation can also be considered in this situation. Although RF ablation (see Chapter 35) of certain types of idiopathic VT (see later) is very effective, ablation for postinfarction VT or that associated with dilated cardiomyopathy is somewhat less effective. In addition, because of the significant mortality associated with these arrhythmias in patients with structural heart disease and depressed LV function, ablation is generally used as an adjunct to ICD placement to reduce the frequency of VT and ICD shocks.¹⁸ However, in patients with well-tolerated postinfarction VT and well-preserved LV function or in patients refractory to drugs, ablation can be used as first-line therapy. In patients with VT or VF, prophylactic ablation of the VT substrate can reduce future shocks.¹⁹

Specific Types of Ventricular Tachycardia

A number of fairly specific types of VT have been identified, and distinction is based on a constellation of ECG and EP features, a specific set of clinical events, and genetics (see Chapter 32). These different types of VT often have different prognoses and responses to different therapy.

Ventricular Arrhythmias in Patients with Cardiomyopathies (see Chapters 54, 65, and 66)

ISCHEMIC CARDIOMYOPATHY. Patients with previous myocardial infarction are at risk for developing VT. In the setting of a remote myocardial infarction, the mechanism of VT is reentry and involves the infarct scar and in particular the border zone or other areas of the scar with deranged conduction. As a result, the VT in this setting is typically monomorphic. More than one morphology can be seen because of different exit sites from the same circuit resulting in different activation patterns of the rest of the ventricle or reversal of the direction of reentry using the same circuit (and resulting in a different ventricular activation pattern) or other circuits existing in the infarct scar. Polymorphic VT or VF in the setting of ischemic heart disease usually occurs during active ischemia or infarction. Treatment of VT in the setting of ischemic heart disease follows the recommendations described earlier. In general, ICDs are indicated to prevent sudden cardiac death from VT, especially in those with depressed LV function. Monomorphic VT in this setting is often amenable to pace termination. In patients with preserved LV function and no hemodynamic compromise, optimal long-term treatment is still controversial. Primary suppression with antiarrhythmic drugs (e.g., amiodarone), implantation with an ICD, antitachycardia pacing, and ablation are options. Newer approaches to ablation of VT caused by a previous infarct scar have increased the efficacy,²⁰ but the recurrence rate is high because of multiple circuits, and ablation is in general reserved for refractory VT or very well tolerated VT (see Chapter 35). Surgical endocardial resection of the scarred area is also an effective treatment of refractory VT caused by previous infarction. For recurrent VT or VT storm refractory to medications or ablation, cardiac sympathetic denervation has been effective in limited studies.²¹

NONISCHEMIC CARDIOMYOPATHY. Both dilated and hypertrophic cardiomyopathy can be associated with VTs and an increased risk for sudden cardiac death (see Chapter 65). Induction of VT by programmed stimulation does not reliably identify high-risk patients. Because it is difficult to predict patients at risk for sudden death or those who might respond favorably to an antiarrhythmic drug, ICDs have been advocated for patients with life-threatening ventricular arrhythmias and dilated cardiomyopathy (see Table 37-8). Bundle branch reentry may be the basis of some VTs in this population and can be treated by ablation of the right bundle branch. In patients with refractory or recurrent VT, ablation is an effective adjunct to an ICD, but ablation from the epicardial surface is often required.²⁰

HYPERTROPHIC CARDIOMYOPATHY. The risk for sudden death in patients with hypertrophic cardiomyopathy (see Chapter 66) is

increased by the presence of syncope, a family history of sudden death in first-degree relatives, septal thickness greater than 3 cm, or the presence of nonsustained VT on 24-hour electrocardiographic recordings.²² Asymptomatic or mildly symptomatic patients with brief and infrequent episodes of nonsustained VT have low mortality. EP testing to risk-stratify for ventricular arrhythmias and sudden death is controversial and has not been shown to reliably identify patients at increased risk. Amiodarone has been useful in some patients with mildly symptomatic, nonsustained VT but not in improving survival. Dual-chamber pacing, septal alcohol ablation, and myotomy/myectomy have been useful in reducing the outflow gradient, but their role in reducing ventricular arrhythmias has not been established. Currently, no totally acceptable way to risk-stratify patients with hypertrophic cardiomyopathy in terms of VT has been identified. In patients believed to be at high risk for sudden death or those with sustained VT or frequent nonsustained VT, an ICD may be indicated.²³

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY. Arrhythmogenic RV cardiomyopathy (also called arrhythmogenic RV dysplasia [ARVD]) is a heterogeneous inherited disease that results in fibrofatty infiltration of predominately the right ventricle, although the disease can also affect the left ventricle (typically the posterior portion) (see Chapter 65). Mutations in genes that encode various proteins of the desmosome (plakoglobin, desmoplakin, plakophilin, desmoglein, and desmocollin) have been found to cause the disease but are present in only approximately 50% of patients.²⁴ Right-sided heart failure or asymptomatic RV enlargement can be present. Male patients predominate, and most are usually found to have an abnormal right ventricle on echocardiography, RV angiography, or magnetic resonance imaging, although this abnormality may not be apparent on initial evaluation. Patients with arrhythmogenic RV cardiomyopathy have VT that generally has a left bundle branch block contour (because the tachycardia arises in the right ventricle) and can have several morphologies (including those consistent with outflow tract VT—see below). The ECG during sinus rhythm can exhibit complete or incomplete right bundle branch block and T wave inversions in V_1 to V_3 . A terminal notch in the QRS, called an epsilon wave, can be present as a result of slowed intraventricular conduction. Findings on the signal-averaged ECG can be abnormal because of delayed conduction in the right ventricle (Fig. 37-30A).

Arrhythmogenic RV cardiomyopathy can be an important cause of ventricular arrhythmia in children and young adults with apparently normal hearts, as well as in older patients. The initial findings can be subtle and often mimic those of outflow tract VT; they are manifested only by tachycardia and no symptoms of right-sided heart failure. Diagnosis of ARVD can be elusive because of nonspecific findings on several tests, depending on the stage and severity of the disease, desmosomal mutations present in only approximately 50% of cases, and low penetrance of the inherited trait. Therefore, the diagnosis of ARVD is based on fulfilling the diagnostic criteria established by the ARVD Task Force to provide guidance on the role of diagnostic tests and specificity (Table 37-9).²⁵ ICDs are generally preferable to pharmacologic approaches because of the progressive nature of the disease and poor prognosis, particularly if the patients have poorly tolerated VT resulting in syncope or sudden cardiac death. RF catheter ablation can be tried but often requires ablation of multiple morphologies, as well as extensive substrate ablation to eliminate all potential reentrant circuits. Because most of the circuits and scarring are located on the epicardial surface, epicardial ablation is often required.

Tetralogy of Fallot

Chronic serious ventricular arrhythmias can occur in patients some years after repair of tetralogy of Fallot (see Chapter 62). Sustained VT after repair can be caused by reentry at the site of previous surgery in the RV outflow tract and can be cured by resection or catheter ablation of this area. Findings on the signal-averaged ECG can be abnormal. Decreased cardiac output can occur during VT and residual RV outflow obstruction and lead to VF. In some cases, worsening of pulmonary insufficiency and RV dilation can trigger the

VT. Replacement of the pulmonic valve and concomitant cryoablation of the outflow tract may be required to eliminate the tachycardia.

Inherited Arrhythmia Syndromes (See Chapter 32)

CATECHOLAMINERGIC POLYMORPHIC VENTRICULAR TACHYCARDIA. Catecholaminergic polymorphic VT (CPVT) is an uncommon form of inherited VT that occurs in the absence of overt structural heart disease.²⁶⁻²⁸ Mutations in genes encoding proteins responsible for intracellular calcium handling have been identified as causes of the disease.²⁹ Patients typically have syncope or aborted sudden death with highly reproducible, stress-induced VT that is often bidirectional. These patients have no structural heart disease and normal QT intervals. A family history of sudden death or stress-induced syncope is present in approximately 30% of cases. During exercise, typical responses include initial sinus tachycardia and ventricular extrasystoles, followed by salvos of monomorphic or bidirectional VT, which eventually lead to polymorphic VT as exercise continues (Fig. 37-31). The treatment of choice is beta blockers²⁸ and an ICD, although breakthrough can occur with beta blockade. Sympathectomy has been reported to be effective in a few cases.²⁸ In addition, flecainide inhibits ryanodine receptor-mediated calcium release in mice and has had some clinical success.²⁸ Patients with CPVT should be instructed to avoid vigorous exercise.

BRUGADA SYNDROME. Brugada syndrome is a distinct form of idiopathic VF in which patients have right bundle branch block and ST-segment elevation in the anterior precordial leads, without any evidence of structural heart disease (Fig. 37-32)³⁰ (see Chapter 32). Findings on the ECG are characterized as type 1, type 2, or type 3 patterns (Table 37-10 and Fig. e37-5). However, because both type 2 and type 3 are characterized by a saddleback morphology of the ST segment and appear to have a similar prognosis, a simpler grouping of type 1 (coved) and type 2 (saddleback) has been proposed. Signature findings on the ECG can be transient, and subtle changes on the ECG similar to these findings can be found in patients without Brugada syndrome. Brugada syndrome should be suspected in patients with a type 1 ECG pattern in more than one right precordial lead (V_1 to V_3) if there is documented VF, polymorphic VT, family history of sudden cardiac death, Brugada-pattern ECG in other family members, or syncope.³¹ Type 2 and type 3 findings on the ECG are not diagnostic of Brugada syndrome. If type 2 or type 3 ECG patterns (in more than one right precordial lead) convert to a type 1 pattern after challenge with procainamide, one should consider the diagnosis of Brugada syndrome if at least one clinical criterion (listed above) is also present.³¹ Mutations in genes responsible for the sodium channel (*SCN5A*) and calcium channel have been identified in many families with Brugada syndrome (see Chapter 32). This syndrome is common in apparently healthy young Southeast Asians but also exists in other areas of the world and ethnicities. The precise mechanism of the changes on the ECG and the development of VF is not known. Heterogeneous loss of the action potential dome in the RV epicardium leads to propagation of the dome from sites where it is maintained to sites where it is lost (phase 2 reentry), thereby resulting in ventricular arrhythmias. Procainamide can expose latent electrocardiographic forms of the syndrome and have been proposed as a provocative test. In contrast, quinidine has been shown to “normalize” the ECG in patients with Brugada syndrome, presumably by blocking the calcium-independent transient outward potassium current (I_{to}), heterogeneity of which may play a pathogenic role. In addition, ablation in the epicardium of the anterior RV outflow tract has also been demonstrated to normalize the ECG, perhaps because of elimination of the I_{to} -rich area of the RV outflow tract.^{32,33} ICDs are the only effective treatment to prevent sudden death. In case reports, quinidine has been shown to be effective in patients with frequent or storms of VT/VF.^{34,35} In patients with VT storm secondary to Brugada syndrome, low-dose isoproterenol has been demonstrated in a few case reports to be effective in suppressing the arrhythmia. EP studies as a means to risk-stratify patients remains controversial, and a recent study suggested that VT/VF inducibility is unable to identify high-risk patients with Brugada syndrome.³⁶ A spontaneous ECG

FIGURE e37-5 Precordial leads of a patient with Brugada syndrome showing dynamic changes on the ECG over the course of several days. The second two ECGs (type 2 and 3) were obtained from the same patient as the first ECG (type 1), just 13 days later. Arrows denote the J wave. (From Wilde AAM, Antzelevitch C, Borggrefe M, et al: Proposed diagnostic criteria for the Brugada syndrome: Consensus report. *Circulation* 106:2514, 2002.)

pattern of Brugada syndrome (type 1), a history of syncope, ventricular refractoriness of less than 200 milliseconds, and QRS fragmentation were the best predictors of a high-risk group.³⁶ A website (www.brugadadrugs.org) has been established to identify drugs causing or interacting with Brugada syndrome.³⁷

Torsades de Pointes

ELECTROCARDIOGRAPHIC RECOGNITION. The term *torsades de pointes* refers to a VT characterized by QRS complexes of changing amplitude that appear to twist around the isoelectric line and occur at rates of 200 to 250/min (Fig. 37-33A). Originally described in the setting of bradycardia caused by complete heart block, torsades de

pointes usually connotes a syndrome, not simply an electrocardiographic description of the QRS complex of the tachycardia, characterized by prolonged ventricular repolarization with QT intervals generally exceeding 500 milliseconds. The U wave can also become prominent and merge with the T wave, but its role is not clear. The abnormal repolarization need not be present or at least prominent in all beats, but it may be apparent only on the beat before the onset of torsades de pointes (i.e., after a PVC). Long-short R-R cycle sequences commonly precede the onset of torsades de pointes from acquired causes. Relatively late PVCs can discharge during termination of the long T wave and precipitate successive bursts of VT, during which the peaks of QRS complexes appear successively on one side and then on the other side of the isoelectric baseline; these peaks give the typical twisting appearance with continuous and progressive changes in QRS contour and amplitude. Torsades de pointes can terminate with progressive prolongation of cycle length and larger and more distinctly formed QRS complexes and culminate in a return to the basal rhythm, a period of ventricular standstill, and a new attack of torsades de pointes or VF.

A less common form, the short-coupled variant of torsades de pointes, is a malignant disease with a high mortality rate that shares several characteristics with idiopathic VF. The ventricular arrhythmia in this setting is initiated with a close-coupled PVC and does not usually involve preceding pauses or bradycardia.

VT that is similar morphologically to torsades de pointes and occurs in patients without QT prolongation, whether spontaneous or electrically induced, should generally be classified as polymorphic VT, not as torsades de pointes. The distinction has important therapeutic implications (see later).

ELECTROPHYSIOLOGIC FEATURES.

The EP mechanisms responsible for torsades de pointes are not completely understood. Most data suggest that early afterdepolarizations (see Chapter 33) are responsible for both

long-QT syndrome and torsades de pointes, or at least its initiation. Perpetuation can be caused by triggered activity, reentry resulting from dispersion of repolarization produced by the early afterdepolarizations, or abnormal automaticity. However, most data currently point to transmural reentry as the most likely mechanism of perpetuation.

CLINICAL FEATURES. Although many predisposing factors have been cited, the most common causes are congenital severe bradycardia, potassium depletion, and use of QT-prolonging medications (such as class IA or III antiarrhythmic drugs). More than 50 drugs have been noted to prolong the QT interval (see later, Long-QT Syndrome). Clinical features depend on whether the torsades de pointes is caused by acquired or congenital (idiopathic) long-QT syndrome (see later).

TABLE 37-9 Diagnostic Criteria for Arrhythmogenic Right Ventricular Cardiomyopathy

Definite diagnosis	2 major criteria <i>or</i> 1 major and 2 minor criteria <i>or</i> 4 minor criteria from different categories
Borderline	1 major and 1 minor criteria <i>or</i> 3 minor criteria from different categories
Possible	1 major <i>or</i> 2 minor criteria from different categories
CRITERIA	
I. Global or Regional Dysfunction and Structural Alterations	
Major criteria	<u>By 2-dimensional echocardiography:</u> Regional RV akinesia, dyskinesia, * or aneurysm <i>and</i> 1 of the following (end diastole): PLAX RVOT ≥ 32 mm (corrected for body size—PLAX/BSA ≥ 19 mm ²) PSAX RVOT ≥ 36 mm (corrected for body size—PSAX/BSA ≥ 21 mm ²) Fractional area change $\leq 33\%$ <u>By MRI:</u> Regional RV akinesia or dyskinesia or dyssynchronous RV contraction <i>and</i> 1 of the following: Ratio of RV end-diastolic volume to BSA ≥ 110 mL/m ² (male) or ≥ 100 mL/m ² (female) RV ejection fraction $\leq 40\%$ <u>By RV angiography:</u> Regional RV akinesia, dyskinesia, or aneurysm
Minor criteria	<u>By 2-dimensional echocardiography:</u> Regional RV akinesia or dyskinesia <i>and</i> 1 of the following (end diastole): PLAX RVOT ≥ 29 to <32 mm (corrected for body size—PLAX/BSA ≥ 16 to ≤ 19 mm ²) PSAX RVOT ≥ 32 to <36 mm (corrected for body size—PSAX/BSA ≥ 18 to <21 mm ²) Fractional area change $>33\%$ to $\leq 40\%$ <u>By MRI:</u> Regional RV akinesia or dyskinesia or dyssynchronous RV contraction <i>and</i> 1 of the following: Ratio of RV end-diastolic volume to BSA ≥ 100 to <110 mL/m ² (male) or ≥ 90 to <100 mL/m ² (female) RV ejection fraction $>40\%$ to $\leq 45\%$
II. Tissue Characterization of Wall	
Major criteria	Residual myocytes $<60\%$ by morphometric analysis (or $<50\%$ if estimated), with fibrous replacement of the RV free wall myocardium in ≥ 1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
Minor criteria	Residual myocytes 60% to 75% by morphometric analysis (or 50% to 65% if estimated), with fibrous replacement of the RV free wall myocardium in ≥ 1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
III. Repolarization Abnormalities	
Major criteria	Inverted T waves in right precordial leads (V ₁ , V ₂ , and V ₃) or beyond in individuals >14 yr (in the absence of complete right bundle branch block QRS ≥ 120 msec)
Minor criteria	Inverted T waves in leads V ₁ and V ₂ in individuals >14 yr (in the absence of complete right bundle branch block) or in V ₄ , V ₅ , or V ₆ Inverted T waves in leads V ₁ , V ₂ , V ₃ , and V ₄ in individuals >14 yr in the presence of complete right bundle branch block
IV. Depolarization/Conduction Abnormalities	
Major criteria	Epsilon wave (reproducible low-amplitude signals between the end of the QRS complex to the onset of the T wave) in the right precordial leads (V ₁ to V ₃)
Minor criteria	Filtered QRS duration (fQRS) ≥ 114 msec Duration of terminal QRS ≤ 40 μ V (low-amplitude signal duration) ≥ 38 msec Root-mean-square voltage of terminal 40 msec ≤ 20 μ V Terminal activation duration of QRS ≥ 55 msec measured from the nadir of the S wave to the end of the QRS, including R', in V ₁ , V ₂ , or V ₃ , in the absence of complete right bundle branch block

Continued

Symptoms from the tachycardia depend on its rate and duration, as with other VTs, and range from palpitations to syncope and death. Women, perhaps because of a longer QT interval, are at greater risk than men for torsades de pointes.

MANAGEMENT. The approach to management of VT with a polymorphic pattern depends on whether it occurs in the setting of a prolonged QT interval. For this practical reason and because the mechanism of the tachycardia can differ according to whether a long QT interval is present, it is important to restrict the definition of torsades de pointes to the typical polymorphic VT in the setting of a long QT or U wave in the basal complexes. In all patients with torsades de

pointes, administration of class IA, possibly some class IC, and class III antiarrhythmic agents (e.g., amiodarone, dofetilide, sotalol) can increase the abnormal QT interval and worsen the arrhythmia. Intravenous magnesium is the initial treatment of choice for torsades de pointes from an acquired cause, followed by temporary ventricular or atrial pacing. Isoproterenol, given cautiously because it may exacerbate the arrhythmia, can be used to increase the rate until pacing is instituted. Lidocaine, mexiletine, or phenytoin can be tried. The cause of the long QT should be determined and corrected, if possible. When the QT interval is normal, polymorphic VT resembling torsades de pointes is diagnosed, and standard antiarrhythmic drugs can be

**TABLE 37-9 Diagnostic Criteria for Arrhythmogenic Right Ventricular Cardiomyopathy—cont'd**

CRITERIA	
V. Arrhythmias	
Major criteria	Nonsustained or sustained VT of left bundle branch morphology with superior axis (negative or indeterminate QRS in leads II, III, and aVF and positive in lead aVL)
Minor criteria	Nonsustained or sustained ventricular tachycardia of RV outflow configuration, left bundle branch block morphology with inferior axis (positive QRS in leads II, III, and aVF and negative in lead aVL) or of unknown axis >500 ventricular extrasystoles per 24 hr (Holter)
VI. Family History/Genetics	
Major criteria	ARVC/D confirmed in a first-degree relative who meets the current task force criteria ARVC/D confirmed pathologically at autopsy or surgery in a first-degree relative Identification of a pathogenic mutation [†] categorized as associated or probably associated with ARVC/D in the patient under evaluation
Minor criteria	History of ARVC/D in a first-degree relative in whom it is not possible or practical to determine whether the family member meets the current task force criteria Premature sudden death (<35 yr) because of suspected ARVC/D in a first-degree relative ARVC/D confirmed pathologically or by current task force criteria in a second-degree relative

*Hypokinesia is not included in this or subsequent definitions of RV regional wall motion abnormalities for the proposed modified criteria.

[†]A pathogenic mutation is a DNA alteration associated with ARVC/D that alters or is expected to alter the encoded protein, is unobserved or rare in a large non-ARVC/D control population, and either alters or is predicted to alter the structure or function of the protein or has demonstrated linkage to the disease phenotype in a conclusive pedigree.

ARVC/D, arrhythmogenic RV cardiomyopathy/dysplasia; aVF = augmented voltage unipolar left foot lead; aVL = augmented voltage unipolar left arm lead; BSA = body surface area; PLAX = parasternal long-axis view; PSAX = parasternal short-axis view; RVOT = RV outflow tract.

From Marcus FI, McKenna WJ, Sherrill D, et al: *Diagnosis of arrhythmogenic right ventricular cardiomyopathy/dysplasia: Proposed modification of the task force criteria. Circulation* 121:1533, 2010.

prescribed. In borderline cases, the clinical context may help determine whether treatment should be initiated with antiarrhythmic drugs. Torsades de pointes resulting from congenital long-QT syndrome is treated with beta blockade, pacing, and ICDs (see later). ECGs obtained from close relatives can help secure the diagnosis of long-QT syndrome in borderline cases.

Long-QT Syndrome

ELECTROCARDIOGRAPHIC RECOGNITION. The upper limit for duration of the normal QT interval corrected for heart rate (QTc) is often given as 0.44 second (see Fig. 37-33B). However, the normal QTc interval may actually be longer (0.46 second in men and 0.47 second in women), with a normal range of $\pm 15\%$ of the mean value. The nature of the U wave abnormality and its relationship to long-QT syndrome are not clear. The probable risk for development of life-threatening ventricular arrhythmias in patients with idiopathic long-QT syndrome is related to the length of the QTc interval, with risk increasing at values of 500 milliseconds or longer. T wave “humps” on the ECG can suggest the presence of long-QT syndrome and can be caused by early afterdepolarizations. Unique T wave contours have been ascribed to specific genotypes causing long-QT syndrome.

CLINICAL FEATURES. Long-QT syndrome can be divided into congenital and acquired forms. The congenital form is a familial disorder that can be associated with sensorineural deafness (Jervell and Lange-Nielsen syndrome, autosomal recessive) or normal hearing (Romano-Ward syndrome, autosomal dominant). Congenital long-QT syndrome is caused by inherited channelopathies created by mutations in one or more genes (see Chapter 32).^{38,39}

Patients with the acquired form may also have an underlying genetic predisposition, with a long QT interval developing from various drugs, such as quinidine, procainamide, *N*-acetylprocainamide, sotalol, amiodarone, disopyramide, phenothiazines, tricyclic antidepressants, erythromycin, pentamidine, some antimalarials, cisapride, and probucol; electrolyte abnormalities, such as hypokalemia and hypomagnesemia; the effects of a liquid protein diet and starvation; central nervous system lesions; significant bradyarrhythmias; cardiac ganglionitis; and mitral valve prolapse. A more comprehensive list that is regularly updated can be found at (<http://crediblemeds.org/healthcare-providers/>).

Patients with congenital long-QT syndrome can initially have syncope, at times misdiagnosed as epilepsy, as a result of torsades de pointes. Sudden death can occur in this group of patients; it develops in approximately 10% of pediatric patients without preceding symptoms. It is obvious that in some patients the ventricular arrhythmia becomes sustained and probably transitions to VF. Patients with long-QT syndrome who are at increased risk for sudden death include those with family members who died suddenly at an early age and those who have experienced syncope. Exercise, particularly swimming, and emotional stress appear to be triggers in LQT1, with lethal cardiac events occurring more frequently at rest or during sleep in LQT3. Patients with LQT2 have many events occurring during emotional stress or a sudden loud noise (e.g., telephone or alarm clock) (see Chapter 32).

Stress testing can prolong the QT interval and produce T wave alternans, the latter indicative of electrical instability. ECGs should be obtained for all family members when the proband has symptoms. Premature ventricular stimulation electrically does not generally induce arrhythmias in this syndrome, and EP studies are not usually helpful in making the diagnosis.

MANAGEMENT. For patients who have long-QT syndrome but not syncope, complex ventricular arrhythmias, a family history of sudden cardiac death, or a QTc interval of 500 milliseconds or longer, no therapy or treatment with a beta blocker is generally recommended. In asymptomatic patients with complex ventricular arrhythmias, a family history of early sudden cardiac death, or a QTc interval of 500 milliseconds or longer, beta adrenoceptor blockers such as nadolol at maximally tolerated doses are recommended. Implantation of a permanent pacemaker to prevent the bradycardia or pauses that may predispose to the development of torsades de pointes may be indicated. In patients with syncope or aborted sudden death, an ICD is warranted. These patients should also be treated with concomitant beta blockers. An ICD is beneficial in these patients, not simply because of its shocking capabilities but also because of the ability to pace continually for prevention of bradycardia-induced torsades and algorithms to prevent post-PVC pauses. Use of an ICD in patients without syncope but with a long QT interval and a strong family history of sudden death is still controversial but may be warranted in selected high-risk patients (see Chapter 36). Left-sided cervicothoracic sympathetic ganglionectomy that interrupts

FIGURE 37-31 ECG obtained during an exercise treadmill test in a patient with CPVT. **A**, During the early phase of exercise, short runs of polymorphic VT and PVCs occur. **B**, With further exercise, bidirectional VT ensues.

FIGURE 37-32 **A**, Twelve-lead ECG of a patient with Brugada syndrome. The ECG is characterized by a right bundle branch block pattern and persistent ST elevation in leads V₁ through V₃. This ECG shows a type 2 Brugada pattern with a “saddleback” ST-segment elevation greater than 1 mm and a biphasic T wave in V₁ (positive in V₂-V₃). **B**, After a procainamide challenge, the prototypic changes on the ECG are exaggerated, with an increase in ST elevation, and the ECG shows a type 1 pattern with a downward-sloping coved ST elevation and negative T waves in V₁-V₃.

TABLE 37-10 Characteristics of Brugada-Pattern Electrocardiograms

	TYPE 1	TYPE 2	TYPE 3
J wave amplitude	≥2 mm	≥2 mm	≥2 mm
T wave	Negative	Positive or biphasic	Positive
ST-T configuration	Coved	Saddleback	Saddleback
ST segment (terminal portion)	Gradually descending	Elevated ≥1 mm	Elevated <1 mm

From Wilde AAM, Antzelevitch C, Borggrefe M, et al: Proposed diagnostic criteria for the Brugada syndrome: Consensus report. *Circulation* 106:2514, 2002.

the stellate ganglion and the first three or four thoracic ganglia may be helpful and can be done with minimal invasion.⁴⁰ Most competitive sports are usually contraindicated in patients with congenital long-QT syndrome.⁴¹ For patients with the acquired form and torsades de pointes, intravenous magnesium and atrial or ventricular pacing are initial choices. Avoidance of precipitating drugs is mandatory.

Short-QT Syndrome

A new inherited syndrome resulting in a short QT interval has recently been found to carry an increased risk for sudden death because of VF and is probably one of the syndromes responsible for “idiopathic VF.” Patients with short-QT syndrome are also prone to the development of atrial fibrillation. Several genetic abnormalities have been

FIGURE 37-33 Torsades de pointes. **A**, Continuous monitor lead recording. A demand ventricular pacemaker (VVI) had been implanted because of a type II second-degree AV block. After treatment with amiodarone for recurrent VT, the QT interval became prolonged (about 640 msec during paced beats), and episodes of torsades de pointes developed. In this recording the tachycardia spontaneously terminates and a paced ventricular rhythm is restored. Motion artifact is noted at the end of the recording as the patient lost consciousness. **B**, Tracing from a young boy with congenital long-QT syndrome. The QTU interval in the sinus beats is at least 600 milliseconds. Note the TU wave alternans in the first and second complexes. A late premature complex occurring in the downslope of the TU wave initiates an episode of VT.

identified, many of which are gain-of-function mutations in the same genes that cause long-QT syndrome (see Chapter 32). Although no clear definition exists of what represents a pathologically short QT as related to outcomes of sudden death, a QTc of less than 350 milliseconds at rates lower than 100 beats/minute, which is more than 2 SD from the mean in a large healthy population, is generally considered short. However, in many patients with short-QT syndrome, the QT does not change with the heart rate, and thus the conventional formulas for QT correction may not apply to patients with short-QT syndrome. A short QT interval on an ECG without a family history of sudden death or a history of syncope, palpitations, or atrial fibrillation may not necessarily indicate an increased risk for sudden death, and similarly, some patients with known short-QT syndrome mutations have QT intervals in the lower range of normal. Patients with short-QT syndrome often have persistently short QT intervals, short or absent ST segments, and tall and narrow T waves in the precordial leads. For reasons stated earlier, the diagnosis of short-QT syndrome can be difficult to make. Diagnostic criteria have been proposed but to date have not been widely accepted.⁴² Other causes of short-QT syndrome, such as hyperkalemia, hypercalcemia, hyperthermia, acidosis, and digitalis, should be excluded. ICDs are considered the treatment of choice in symptomatic patients to prevent sudden cardiac death. Antiarrhythmic drugs that prolong refractoriness have been reported to be effective in some patients. In particular, quinidine has been shown to be effective in patients with a gain-of-function mutation in the *HERG* (*KCNH2*) gene.

J Wave Syndrome

The J wave is the junction of the QRS complex and the ST segment on a surface ECG and is also referred to as the Osborn wave. J wave syndrome is part of the spectrum of early repolarization that can lead to ventricular arrhythmias (polymorphic VT and VF); it also includes Brugada syndrome and short-QT syndrome (both described previously). J wave syndrome is distinct from these two entities by the magnitude and lead location and has an ECG pattern of early repolarization—J point elevation in the inferior or lateral precordial leads. Occasionally, the J point elevation can be noted in all leads. In addition, ischemia and hypothermia can also have similar effects on the ECG and predispose to arrhythmias. These early repolarization syndromes (inherited and acquired), however, seem to be linked mechanistically to abnormalities in the I_{to} current⁴³ (see Chapter 33). In a retrospective registry of 100 patients with unexplained cardiac arrest, J point elevation of 0.1 mV or greater was present in the inferior-lateral leads in 23% of those with unexplained cardiac arrest (idiopathic VF).⁴⁴ However, this association does not establish a causal link, and it remains unknown what the incidence of ventricular arrhythmias is in those with J wave syndromes. Early repolarization is commonly seen in healthy individuals (typically in men and athletes) but is often restricted to leads I and V_4 to V_6 on the ECG. Most patients with early repolarization are not at risk for ventricular arrhythmias, and specific criteria for determining risk have not been developed. However, J point elevation greater than 0.2 mV associated with a short QTc or distinct J waves should raise suspicion, particularly when they appear in the inferior leads (II, III, and aVF) or on all precordial and limb leads of a 12-lead ECG and the ST segment is flat or downsloping.^{43,45}

Idiopathic Ventricular Tachycardias

Idiopathic VT is defined as monomorphic VT in patients without any structural heart disease or coronary disease. When more than one morphology of VT is present, one should suspect other disease entities, such as ARVD. Idiopathic VTs have any one of several characteristic electrocardiographic morphologies representing three distinct entities based on the location of the VT—outflow tract tachycardias, annular tachycardias, and fascicular tachycardias. The prognosis for all forms of idiopathic monomorphic VT without structural heart disease is good. They are amenable to ablation and frequently respond well to drug therapy.

OUTFLOW TRACT TACHYCARDIAS. Idiopathic VTs with monomorphic contours can be divided into at least three types. Two types, paroxysmal VT and repetitive monomorphic VT, appear to originate from the region of the RV outflow tract (Figs. 37-34 and 37-35) or the LV outflow tract. Rarely, the VT can originate from the proximal pulmonary artery (just beyond the pulmonic valve or from the cusps of the aortic valve). RV outflow tract VTs have a characteristic electrocardiographic appearance of a left bundle branch block contour in V_1 and an inferior axis in the frontal plane. Vagal maneuvers, including adenosine, can terminate the VT, whereas exercise, stress, isoproterenol infusion, and rapid or premature stimulation often initiate or perpetuate the tachycardia. Beta blockers and verapamil can suppress this tachycardia as well. The paroxysmal form is induced by exercise or stress, whereas the repetitive monomorphic type occurs at rest, with sinus beats interposed between runs of nonsustained VT that may be precipitated by transient increases in sympathetic activity unrelated to exertion. In a small number of patients, the tachycardia seems to arise in the inflow tract or apex of the right ventricle. A similar tachycardia has been identified in the LV outflow tract and may mimic that of RV outflow tract tachycardia. A distinguishing feature on the ECG is the presence of an S wave in lead I and an early precordial R wave transition (V_1 to V_2) during LV outflow tract VT.⁴⁶ The prognosis for most patients with outflow tract (RV or LV) VT is good. RF catheter ablation effectively eliminates this focal tachycardia in symptomatic patients. In others, antiarrhythmic drugs can be effective.

ANNULAR VENTRICULAR TACHYCARDIAS. VTs arising from the mitral or tricuspid annulus account for between 4% and 7% of cases of idiopathic VT. Most often they are of the repetitive monomorphic

FIGURE 37-34 VT originating from the RV outflow tract. This tachycardia is characterized by a left bundle branch block contour in lead V₁ and an inferior axis.

FIGURE 37-35 **A**, Repetitive monomorphic VT. Short episodes of a monomorphic VT at a rate of 160 beats/min repeatedly interrupt the normal sinus rhythm. Retrograde atrial capture probably occurs (the arrowhead points to the deflection in the ST segment), and the retrograde P wave of the last complex of the repetitive monomorphic VT conducts over the normal pathway to produce a QRS complex with a normal contour. **B**, Short runs of a very rapid (260 beats/min) VT of uniform contour. They probably provoke a compensatory sympathetic response because each is followed by a brief period of sinus tachycardia. The sinus pacemaker appears to be unstable because of the resultant changes in P wave morphology.

type. For mitral annular VT, the electrocardiographic morphology is typically a right bundle branch block pattern (transition in V₁ or V₂), S wave in V₆, and monophasic R or Rs in leads V₂ through V₆. For tricuspid annular VT, the foci generally originate in the septal region, and thus the typical finding on the ECG is a left bundle branch block pattern (Qs in lead V₁), an early transition in precordial leads (V₃), and narrower QRS complexes. These VTs behave similarly to outflow tract VT, both in prognosis and in drug response. Annular VTs are amenable to ablation.

FASCICULAR VENTRICULAR TACHYCARDIA (LEFT SEPTAL VENTRICULAR TACHYCARDIA). A left septal VT has been described as most often arising in the left posterior septum, frequently preceded by a fascicular potential, and is sometimes called a fascicular tachycardia (Fig. 37-36). The tachycardias most commonly arise from the left posterior fascicle but can also arise (or exit) from the anterior fascicle. Because they arise from the fascicle, the VT appearance on an ECG typically has a rapid initial component and resembles either

a typical left anterior fascicular block (for those arising from the posterior fascicle) or, less commonly, a typical left posterior fascicular block (for those arising from the anterior fascicle). Entrainment has been demonstrated, which suggests reentry as a cause of some of the tachycardias. Verapamil or diltiazem often suppresses this tachycardia, whereas adenosine does so only rarely, thus suggesting that the slow inward current may be important. Several mechanisms may be operative, and the group may not be homogeneous. Once it is initiated, the tachycardia is paroxysmal and sustained. It can be started by rapid atrial or ventricular pacing and sometimes by exercise or isoproterenol. The prognosis is generally good. RF catheter ablation is effective in symptomatic patients.

Idiopathic Ventricular Fibrillation

Idiopathic VF can occur in approximately 1% to 8% of individuals with

out-of-hospital VF. Findings on cardiovascular evaluation are normal, except for the arrhythmia. Monomorphic VT is rarely induced at EP study. Its natural history is incompletely known, but recurrences are not uncommon. It is important in this entity, as well as in idiopathic VT, to remember that the arrhythmia may at times be an early manifestation of a developing cardiomyopathy, at least in some patients. There is overlap of idiopathic VF with short-QT syndrome and J wave syndrome (see earlier). However, it is unclear whether early repolarization in the general population carries any additional risk for VF. In some instances, short-coupled PVCs can trigger VF (Fig. 37-37). In patients with idiopathic VF, ICDs are a useful therapeutic choice. Ablation of short-coupled PVCs that trigger VF, often from Purkinje fibers, has also been shown to be effective in reducing recurrence.⁴⁷

Bidirectional Ventricular Tachycardia. Bidirectional VT is an uncommon type of VT characterized by QRS complexes with a right bundle branch block pattern, polarity in the frontal plane alternating from -60 to -90 degrees to +120 to +130 degrees, and a regular rhythm. The ventricular rate is between 140 and 200 beats/minute. Although the mechanism and site of origin of this tachycardia have remained somewhat controversial, most evidence supports a ventricular origin.

Bidirectional VT can be a manifestation of digitalis excess, typically in older patients and those with severe myocardial disease. When the tachycardia is caused by digitalis, the extent of toxicity is frequently advanced, and the prognosis is poor. As the use of digitalis has decreased, this form of VT has become very uncommon. When seen in the absence of digitalis, a diagnosis of CPVT should be considered (see earlier).

Bundle Branch Reentrant Ventricular Tachycardia. VT secondary to bundle branch reentry is characterized by a QRS morphology determined by the circuit established over the bundle branches or fascicles. Retrograde conduction over the left bundle branch system and anterograde conduction over the right bundle branch create a QRS complex with a left bundle branch block contour and constitute the most common form. The frontal plane axis may be approximately +30 degrees. Conduction in the opposite direction produces a right bundle branch block contour. Reentry can also occur over the anterior and posterior fascicles. Electrophysiologically, bundle branch reentrant complexes are started after a critical S₂-H₂ or S₃-H₃ delay. The H-V interval of the bundle branch reentrant complex equals or exceeds the H-V interval of the spontaneous, normally conducted QRS complex.

Bundle branch reentry is a form of monomorphic sustained VT that is usually seen in patients with structural heart disease, such as dilated

FIGURE 37-36 Left septal VT. This tachycardia is characterized by a right bundle branch block contour. In this instance the axis was rightward. The site of the VT was established to be in the left posterior septum by EP mapping and ablation.

FIGURE 37-37 Tracings from a patient with idiopathic VF as a result of short-coupled PVCs. **A**, ECG showing frequent, spontaneous short-coupled PVCs occurring on the late phase of the T wave. **B**, When the PVCs take place during bradycardia, they occur in the early phase of the T wave and produce a short run of VF. **C**, Spontaneous VF in the same patient after another short-coupled spontaneous PVC.

FIGURE 37-38 Ventricular flutter and VF. **A**, The sine wave appearance of the complexes occurring at a rate of 300 beats/min is characteristic of ventricular flutter. **B**, The irregular undulating baseline typifies VF.

cardiomyopathy, and generally in the setting of a wide QRS during sinus rhythm because of an intraventricular conduction delay. Uncommonly, bundle branch reentry can occur in the absence of myocardial disease.

The therapeutic approach is as for other types of VT; however, ablation is very effective. In the acute setting, pace termination is frequently effective.

Ventricular Flutter and Fibrillation Electrocardiographic Recognition

Ventricular flutter and ventricular fibrillation (see Chapter 39) are arrhythmias that represent severe derangements of the heartbeat that can terminate fatally or produce significant brain damage within 3 to 5 minutes unless corrective measures are undertaken promptly. Ventricular flutter is manifested as a sine wave in appearance—regular large oscillations occurring at a rate of 150 to 300 beats/minute (usually about 200) (Fig. 37-38A). Distinction between rapid VT and ventricular flutter can be difficult and is usually of academic interest only. Hemodynamic collapse is present with both. VF is recognized by the presence of irregular undulations of varying contour and amplitude (Fig. 37-38B). Distinct QRS complexes, ST segments, and T waves are absent. Fine-amplitude fibrillatory waves (0.2 mV) are present with prolonged VF. These fine waves identify patients with worse survival rates and are sometimes confused with asystole.

Mechanisms

VF occurs in various clinical situations but most commonly in association with coronary artery disease and as a terminal event (see Chapters 39, 51, and 52). Cardiovascular events, including sudden cardiac death from VF, occur most frequently in the morning. VF can occur during antiarrhythmic drug administration, hypoxia, ischemia, or atrial fibrillation that results in very rapid ventricular rates in patients with preexcitation syndrome; after electrical shock administered during cardioversion (see Chapters 35 and 36) or accidentally by improperly grounded equipment; and during competitive ventricular pacing to terminate VT. It has been reported following the deployment of electronic control devices.⁴⁸

Clinical Features

Ventricular flutter or VF results in faintness, followed by loss of consciousness, seizures, apnea, and eventually, if the rhythm continues untreated, death. Blood pressure is unobtainable, and heart sounds are usually absent. The atria can continue to beat at an independent rhythm for a time or in response to impulses from the fibrillating ventricles. Eventually, electrical activity of the heart ceases (see Chapter 39).

Management

Management should follow basic life support and advanced cardiac life support guidelines (see Chapter

39). Immediate nonsynchronized DC electrical shock using 200 to 400 J is mandatory therapy for VF, ventricular flutter, and pulseless VT. Cardiopulmonary resuscitation is performed only until the defibrillation equipment is ready or if the “downtime” has been long. Defibrillation requires fewer joules if it is done early. If the circulation is markedly inadequate despite return to sinus rhythm, closed-chest massage should be instituted. The use of anesthesia during electrical shock is obviously dictated by the patient's

condition but is not generally required. After conversion of the arrhythmia to a normal rhythm, it is essential to monitor the rhythm continuously and to institute measures to prevent recurrence. Metabolic acidosis quickly follows cardiovascular collapse. If the arrhythmia is terminated within 30 to 60 seconds, significant acidosis does not occur (see Chapter 39).

BRADYARRHYTHMIAS

Bradyarrhythmia is arbitrarily defined as a heart rate below 60 beats/minute. Frequently, bradyarrhythmias are physiologic, as in well-conditioned athletes with low resting heart rates or type I AV block during sleep, and in other cases are pathologic. Similar to tachyarrhythmias, bradyarrhythmias can be categorized on the basis of the level of disturbance in the hierarchy of the normal impulse generation and conduction system (from sinus node to AV node to His-Purkinje system).

Sinus Bradycardia Electrocardiographic Recognition

Sinus bradycardia (Fig. 37-39A) is diagnosed in an adult when the sinus node discharges at a rate slower than 60 beats/minute. P waves have a normal contour and occur before each QRS complex, usually with a constant PR interval longer than 120 milliseconds. Sinus arrhythmia often coexists.

Clinical Features

Sinus bradycardia can result from excessive vagal or decreased sympathetic tone, as an effect of medications, or from anatomic changes in the sinus node. In most cases, symptomatic sinus bradycardia is due to the effects of medication. Asymptomatic sinus bradycardia frequently occurs in healthy young adults, particularly well-trained athletes, and decreases in prevalence with advancing age. During sleep, the normal heart rate can fall to 39 to 40 beats/minute, especially in adolescents and young adults, with marked sinus arrhythmia sometimes producing pauses of 2 seconds or longer. Eye surgery, coronary arteriography, meningitis, intracranial tumors, increased intracranial pressure, cervical and mediastinal tumors, and certain disease states (such as severe hypoxia,

FIGURE 37-39 **A**, Sinus bradycardia at a rate of 40 to 48 beats/min. The second and third QRS complexes (arrowheads) represent junctional escape beats. Note the P waves at the onset of the QRS complex. **B**, Nonrespiratory sinus arrhythmia occurring as a consequence of digitalis toxicity. Monitor leads were used.

myxedema, hypothermia, fibrodegenerative changes, convalescence from some infections, gram-negative sepsis, and mental depression) can produce sinus bradycardia. Sinus bradycardia also occurs during vomiting or vasovagal syncope (see Chapter 40) and can be produced by carotid sinus stimulation or by the administration of parasympathomimetic drugs, lithium, amiodarone, beta adrenoceptor-blocking drugs, clonidine, propafenone, ivabradine (a specific I_f pacemaker current blocker; see Chapter 33), or calcium antagonists. Conjunctival instillation of beta blockers for glaucoma can produce sinus or AV nodal abnormalities, especially in the elderly.

In most cases, sinus bradycardia is a benign arrhythmia and can actually be beneficial by producing a longer period of diastole and increasing ventricular filling time. It can be associated with syncope caused by an abnormal autonomic reflex (cardioinhibitory; see Chapter 40). Sinus bradycardia occurs in 10% to 15% of patients with acute myocardial infarction and may be even more prevalent when patients are seen in the early hours of infarction. Unless it is accompanied by hemodynamic decompensation or arrhythmias, sinus bradycardia is generally associated with a more favorable outcome after myocardial infarction than sinus tachycardia is. It is usually transient and occurs more commonly during inferior than during anterior myocardial infarction; it has also been noted during reperfusion with thrombolytic agents (see Chapter 55). Bradycardia that follows resuscitation from cardiac arrest is associated with a poor prognosis.

Management

Treatment of sinus bradycardia per se is not usually necessary unless cardiac output is inadequate or arrhythmias result from the slow rate. Atropine (0.5 mg intravenously as an initial dose, repeated if necessary) is generally effective acutely; lower doses, particularly given subcutaneously or intramuscularly, can exert an initial parasympathomimetic effect, possibly via a central action. For recurrent symptomatic episodes, temporary or permanent pacing may be needed (see Chapters 35 and 36). As a general rule, no drugs are available that increase the heart rate reliably and safely during long periods without important side effects.

can suppress subsidiary pacemakers located in the ventricles, as well as in supraventricular structures.

Clinical Features

Two types of hypersensitive carotid sinus responses are noted. Cardioinhibitory carotid sinus hypersensitivity is generally defined as ventricular asystole exceeding 3 seconds during carotid sinus stimulation, although normal limits have not been definitively established. In fact, asystole exceeding 3 seconds during carotid sinus massage is not common but can occur in asymptomatic subjects (see Fig. 37-40). Vasodepressor carotid sinus hypersensitivity is usually defined as a decrease in systolic blood pressure of 50 mm Hg or more without associated cardiac slowing or a decrease in systolic blood pressure exceeding 30 mm Hg when the patient's symptoms are reproduced.

Even if a hyperactive carotid sinus reflex is elicited in patients, particularly in older patients who complain of syncope or presyncope, the hyperactive reflex elicited with carotid sinus massage may not necessarily be responsible for these symptoms. Direct pressure or extension of the carotid sinus as a result of head turning, neck tension, and tight collars can also be a source of syncope by reducing blood flow through the cerebral arteries. Hypersensitive carotid sinus reflex is most commonly associated with coronary artery disease. The mechanism responsible for hypersensitive carotid sinus reflex is not known.

Management

Atropine abolishes cardioinhibitory carotid sinus hypersensitivity. However, most symptomatic patients require pacemaker implantation. Because AV block can occur during periods of hypersensitive carotid reflex, some form of ventricular pacing, with or without atrial pacing, is generally required. Atropine and pacing do not prevent the decrease in systemic blood pressure in the vasodepressor form of carotid sinus hypersensitivity, which may result from inhibition of sympathetic vasoconstrictor nerves and possibly from activation of cholinergic sympathetic vasodilator fibers. Combinations of vasodepressor and cardioinhibitory types can occur, and vasodepression can account for continued syncope after pacemaker implantation in some patients. Patients who have a hyperactive carotid sinus reflex that does not cause symptoms require no treatment. Drugs such as digitalis, methyldopa, clonidine, and propranolol can enhance the

Sinus Arrhythmia

Hypersensitive Carotid Sinus Syndrome

Electrocardiographic Recognition

Hypersensitive carotid sinus syndrome (Fig. 37-40) is characterized most frequently by ventricular asystole caused by cessation of atrial activity as a result of sinus arrest or SA exit block. AV block is observed less frequently, probably in part because the absence of atrial activity from sinus arrest precludes the manifestations of AV block. However, if an atrial pacemaker maintained an atrial rhythm during the episodes, a higher prevalence of AV block would probably be noted. In symptomatic patients, AV junctional or ventricular escapes generally do not occur or are present at very slow rates, thus suggesting that heightened vagal tone and sympathetic withdrawal

FIGURE 37-40 **A**, Right carotid sinus massage (RCSM, arrow) results in sinus arrest and a ventricular escape beat (probably fascicular) 5.4 seconds later. Sinus discharge then resumes. **B**, Carotid sinus massage (CSM, arrow; monitor lead) results in slight sinus slowing but, more important, advanced AV block. Obviously, an atrial pacemaker without ventricular pacing would be inappropriate for this patient. HBE = His bundle electrogram; HRA = high right atrial electrogram.

Sinus arrhythmia (see Fig. 37-39B) is characterized by a phasic variation in sinus cycle length during which the maximum sinus cycle length minus the minimum sinus cycle length exceeds 120 milliseconds or the maximum sinus cycle length minus the minimum sinus cycle length divided by the minimum sinus cycle length exceeds 10%. It is the most frequent form of arrhythmia and is considered to be a normal event. P wave morphology does not usually vary, and the PR interval exceeds 120 milliseconds and remains unchanged because the focus of discharge remains relatively fixed within the sinus node. On occasion, the pacemaker focus can wander within the sinus node, or its exit to the atrium may change and produce P waves of a slightly different contour (but not retrograde) and a slightly changing PR interval that exceeds 120 milliseconds.

Sinus arrhythmia commonly occurs in the young, especially those with slower heart rates or after enhanced vagal tone, such as following the administration of digitalis or morphine, and decreases with age or with autonomic dysfunction, such as in diabetic neuropathy. Sinus arrhythmia appears in two basic forms. In the respiratory form, the P-P interval cyclically shortens during inspiration, primarily as a result of reflex inhibition of vagal tone, and slows during expiration; breath-holding eliminates the variation in cycle length (see Chapter 34). Nonrespiratory sinus arrhythmia is characterized by a phasic variation in the P-P interval unrelated to the respiratory cycle and may be the result of digitalis intoxication. Loss of sinus rhythm variability is a risk factor for sudden cardiac death (see Chapter 39).

Symptoms produced by sinus arrhythmia are uncommon, but on occasion, if the pauses between beats are excessively long, palpitations or dizziness may result. Marked sinus arrhythmia can produce a sinus pause sufficiently long to cause syncope if it is not accompanied by an escape rhythm.

Treatment is usually unnecessary. Increasing the heart rate by exercise or drugs generally abolishes sinus arrhythmia. Symptomatic individuals may experience relief from palpitations with sedatives, tranquilizers, atropine, ephedrine, or isoproterenol administration, as for the treatment of sinus bradycardia.

Ventriculophasic Sinus Arrhythmia

The most common example of ventriculophasic sinus arrhythmia occurs during complete AV block and a slow ventricular rate, when P-P cycles that contain a QRS complex are shorter than P-P cycles without a QRS complex. Similar lengthening can be present in the P-P cycle that follows a PVC with a compensatory pause. Alterations in the P-P interval are probably caused by the influence of the autonomic nervous system responding to changes in ventricular stroke volume.

Sinus Pause or Sinus Arrest

Sinus pause or sinus arrest (Fig. e37-6) is recognized by a pause in the sinus rhythm. The P-P interval delimiting the pause does not equal a multiple of the basic P-P interval. Differentiation of sinus arrest, which is thought to be caused by slowing or cessation of spontaneous sinus nodal automaticity and therefore a disorder of impulse formation, from SA exit block (see later) in patients with sinus arrhythmia can be difficult without direct recordings of sinus node discharge.

Failure of sinus nodal discharge results in the absence of atrial depolarization and in periods of ventricular asystole if escape beats initiated by latent pacemakers do not occur (see Fig. e37-6). Involvement of the sinus node by acute myocardial infarction, degenerative fibrotic changes, effects of digitalis toxicity, stroke, or excessive vagal tone can produce sinus arrest. Transient sinus arrest may have no clinical significance by itself if latent pacemakers promptly escape to prevent ventricular asystole or the genesis of other arrhythmias precipitated by the slow rates. Sinus arrest and AV block have been demonstrated in many patients with sleep apnea (see Chapter 75).

Treatment is as outlined earlier for sinus bradycardia. In patients who have a chronic form of sinus node disease characterized by marked sinus bradycardia or sinus arrest, permanent pacing is often necessary. However, as a general rule, chronic pacing for sinus bradycardia is indicated only in symptomatic patients or those with a sinus pause exceeding 3 seconds.

FIGURE e37-6 Sinus arrest. The patient had a long-term electrocardiographic recorder connected when he died suddenly of cardiac standstill. The rhythms demonstrate progressive sinus bradycardia and sinus arrest at 8:41 AM. The rhythm then becomes a ventricular escape rhythm, which progressively slows and finally ceases at 8:47 AM. A monitor lead is shown. The double electrocardiographic strips are continuous recordings.

Sinoatrial Exit Block

SA exit block is an arrhythmia that is recognized electrocardiographically by a pause resulting from absence of the normally expected P wave (**Fig. e37-7**). The duration of the pause is a multiple of the basic P-P interval. SA exit block is caused by a conduction disturbance during which an impulse formed within the sinus node fails to depolarize the atria or does so with delay (**Fig. e37-8**). An interval without P waves that equals approximately two, three, or four times the normal P-P cycle characterizes type II second-degree SA exit block. During type I (Wenckebach) second-degree SA exit block, the P-P interval progressively shortens before the pause, and the duration of the pause is less than two P-P cycles. (See **Chapter 34** for further discussion of Wenckebach intervals.) First-degree SA exit block cannot be recognized on the ECG because SA nodal discharge is not recorded. Third-degree SA exit block can be manifested as a complete absence of P waves and is difficult to diagnose with certainty without sinus node electrograms.

Excessive vagal stimulation, acute myocarditis, infarction, or fibrosis involving the atrium, as well as drugs such as quinidine, procainamide, and digitalis, can produce SA exit block. SA exit block is usually transient. It may be of no clinical importance except to prompt a search for the underlying cause. On occasion, syncope can result if the SA block is prolonged and unaccompanied by an escape rhythm. SA exit block can occur in well-trained athletes.

Therapy for patients who have symptomatic SA exit block is as outlined earlier for sinus bradycardia.

Wandering Pacemaker

This variant of sinus arrhythmia involves passive transfer of the dominant pacemaker focus from the sinus node to latent pacemakers that have the next highest degree of automaticity located in other atrial sites (usually lower in the crista terminalis) or in AV junctional tissue. The change occurs in a gradual fashion over the duration of several beats; thus, only one pacemaker at a time controls the rhythm, in sharp contrast to AV dissociation. The ECG (**Fig. e37-9**) displays a cyclical increase in the R-R interval—a PR interval that gradually shortens and can become less than 120 milliseconds and a change in the P wave contour that becomes negative in lead I or II (depending on the site of discharge) or is lost within the QRS complex. In general, these changes occur in reverse as the pacemaker shifts back to the sinus node. Wandering pacemaker is a normal phenomenon that often occurs in the very young and particularly in athletes, presumably because of augmented vagal tone. Persistence of an AV junctional rhythm (see **Figs. e37-10** and **e37-11**) for long periods, however, may indicate underlying heart disease. Treatment is not usually indicated but, if necessary, is the same as that for sinus bradycardia (see earlier).

FIGURE e37-7 Sinus nodal exit block. **A**, A type I SA nodal exit block has the following features. The P-P interval shortens from the first to the second cycle in each grouping, followed by a pause. The duration of the pause is less than twice the shortest cycle length, and the cycle after the pause exceeds the cycle before the pause. The PR interval is normal and constant. Lead V₁ is shown. **B**, The P-P interval varies slightly because of sinus arrhythmia. The two pauses in sinus nodal activity equal twice the basic P-P interval and are consistent with a type II 2:1 SA nodal exit block. The PR interval is normal and constant. Lead III recording is shown.

FIGURE e37-8 Sinus node exit block. After a period of atrial pacing (only the last paced cycle is shown), a sinus node exit block developed. The tracing demonstrates sinus node potentials (arrowheads), recorded with a catheter electrode, not conducting to the atrium until the last complex. Recordings are leads I, II, III, and V₁, right atrial recording, sinus node recording, and RV apical recording. The bottom tracing is femoral artery blood pressure.

B6-550470

FIGURE e37-9 Wandering atrial pacemaker. As the heart rate slows, the P waves become inverted and then gradually revert toward normal when the heart rate speeds up again. The PR interval shortens to 0.14 second with the inverted P wave and is 0.16 second with the upright P wave. This phasic variation in cycle length with varying P wave contour suggests a shift in pacemaker site and is characteristic of a wandering atrial pacemaker.

FIGURE e37-10 AV junctional rhythm. **Top**, AV junctional discharge occurs fairly regularly at a rate of approximately 50 beats/min. Retrograde atrial activity follows each junctional discharge. **Bottom**, Recording made on a different day in the same patient. The AV junctional rate is slightly more variable, and retrograde P waves precede onset of the QRS complex. The positive terminal portion of the P wave gives the appearance of AV dissociation, which was not present.

FIGURE e37-11 Nonparoxysmal AV junctional tachycardia. **A**, Control. **B**, Response to carotid sinus massage. **C**, Response to atropine, 1 mg intravenously. Note that His bundle depolarization is the earliest recordable electrical activity in each cycle. The atria are depolarized retrogradely (low right atrial activity recorded in the BHE precedes high right atrial activity recorded in the BAE). Note also that carotid sinus massage slows the junctional discharge rate whereas atropine speeds it up. From these tracings alone, one could not distinguish the rhythm from some other types of supraventricular tachycardia. However, the onset and termination of this tachycardia were typical of nonparoxysmal AV junctional tachycardia. BAE = bipolar atrial electrogram; BHE = bipolar His electrogram

FIGURE 37-41 Continuous recording from an implanted loop recorder in a patient with syncope. The tracing shows paroxysmal sinus node arrest and a sinus pause of nearly 30 seconds. The preceding sinus cycle length appears to lengthen just before the pause, which suggests an autonomic component of the pause. There is also a single ventricular escape complex at 14:10:48.

FIGURE 37-42 Sick sinus syndrome with bradycardia-tachycardia. **Top**, Intermittent sinus arrest is apparent with junctional escape beats at irregular intervals (red circles). **Bottom**, In this continuous monitor lead recording, a short episode of atrial flutter is followed by almost 5 seconds of asystole before a junctional escape rhythm resumes. The patient became presyncopal at this point.

response to carotid sinus massage and be responsible for symptoms in some patients. Elastic support hose and sodium-retaining drugs may be helpful in patients with vasodepressor responses.

Sick Sinus Syndrome

Electrocardiographic Recognition

Sick sinus syndrome is a term applied to a syndrome encompassing a number of sinus nodal abnormalities, including (1) persistent spontaneous sinus bradycardia not caused by drugs and inappropriate for the physiologic circumstance, (2) sinus arrest or exit block (**Fig. 37-41**), (3) combinations of SA and AV conduction disturbances, and (4) alternation of paroxysms of rapid regular or irregular atrial tachyarrhythmias and periods of slow atrial and ventricular rates (bradycardia-tachycardia syndrome; **Fig. 37-42**). More than one of these conditions can be recorded in the same patient on different occasions, and their mechanisms can often be shown to be causally interrelated and combined with an abnormal state of AV conduction or automaticity.

Patients with sinus node disease can be categorized as having intrinsic sinus node disease unrelated to autonomic abnormalities or combinations of intrinsic and autonomic abnormalities. Symptomatic patients with sinus pauses or SA exit block frequently show abnormal responses on EP testing and can have a relatively high incidence of atrial fibrillation. In children, sinus node dysfunction most commonly occurs in those with congenital or acquired heart disease, particularly after corrective cardiac surgery. Sick sinus syndrome can occur in the absence of other cardiac abnormalities. The course of the disease is frequently intermittent and unpredictable because it is influenced by the severity of the underlying heart disease. Excessive physical training can heighten vagal tone and produce syncope

related to sinus bradycardia or AV conduction abnormalities in otherwise normal individuals.

The anatomic basis of sick sinus syndrome can involve total or subtotal destruction of the sinus node, areas of nodal-atrial discontinuity, inflammatory or degenerative changes in the nerves and ganglia surrounding the node, and pathologic changes in the atrial wall. Fibrosis and fatty infiltration occur, and the sclerodegenerative processes generally involve the sinus node and the AV node or the bundle of His and its branches or distal subdivisions. Occlusion of the sinus node artery may be important.

Management

For patients with sick sinus syndrome, treatment depends on the basic rhythm problem but usually involves permanent pacemaker implantation when symptoms are manifested (**see Chapter 36**). Pacing for the bradycardia, combined with drug therapy to treat the tachycardia, is required in those with bradycardia-tachycardia syndrome.

ATRIOVENTRICULAR BLOCK (HEART BLOCK)

Heart block is a disturbance of impulse conduction that can be permanent or transient, depending on the anatomic or functional impairment. It must be distinguished from interference, a normal phenomenon that is a disturbance of impulse conduction caused by physiologic refractoriness resulting from inexcitability secondary to a preceding impulse. Interference or block can occur at any site where impulses are conducted, but they are recognized most commonly between the sinus node and atrium (SA block), between the atria and ventricles (AV block), within the atria (intra-atrial block), or within the ventricles (intraventricular block). SA exit block was discussed earlier (**see Sinus Bradycardia**). An AV block exists if the atrial impulse is conducted with delay or is not conducted at all to the ventricle when the AV junction is not physiologically refractory. During AV block, the block can occur in the AV node, His bundle, or bundle branches. In some cases of bundle branch block, the impulse may only be delayed and not completely blocked in the bundle branch, yet the resulting QRS complex may be indistinguishable from a QRS complex generated by a complete bundle branch block.

The conduction disturbance is classified by severity into three categories. During first-degree heart block, conduction time is prolonged but all impulses are conducted. Second-degree heart block occurs in two forms, Mobitz type I (Wenckebach) and type II. Type I heart block is characterized by progressive lengthening of the conduction time until an impulse is not conducted. Type II heart block denotes an occasional or repetitive sudden block of conduction of an impulse, without prior measurable lengthening of conduction time. When no impulses are conducted, complete or third-degree block is present. The degree of block may depend in part on the direction of impulse propagation. For unknown reasons, normal retrograde conduction can occur in the presence of advanced anterograde AV block. The reverse can also occur. Some electrocardiographers use the term *advanced or high-grade heart block* to indicate blockage of two or more consecutive impulses.

First-Degree Atrioventricular Block

During first-degree AV block, every atrial impulse is conducted to the ventricles and a regular ventricular rate is produced, but the PR interval exceeds 0.20 second in adults. PR intervals as long as 1.0 second have been noted and can at times exceed the P-P interval, a phenomenon known as skipped P waves. Clinically important PR interval prolongation can result from a conduction delay in the AV node (A-H interval), in the His-Purkinje system (H-V interval), or at both sites. Equally delayed conduction over both bundle branches can uncommonly produce PR prolongation without significant QRS complex aberration. On occasion, an intra-atrial conduction delay can result in PR prolongation. If the QRS complex on the scalar ECG is normal in contour and duration, the AV delay almost always resides in the AV node and rarely within the His bundle itself. If the QRS complex shows a bundle branch block pattern, the conduction delay may be within the AV node or the His-Purkinje system (Fig. 37-43). In the latter case, a His bundle ECG is necessary to localize the site of conduction delay. Acceleration of the atrial rate or enhancement of vagal tone by carotid massage can cause first-degree AV nodal block to progress to type I second-degree AV block. Conversely, type I second-degree AV nodal block can revert to a first-degree block with deceleration of the sinus rate.

FIGURE 37-43 First-degree AV block. One complex during sinus rhythm is shown. **Left panel**, The PR interval measured 370 milliseconds (PA = 25 msec; A-H = 310 msec; H-V = 39 msec) during a right bundle branch block. Conduction delay in the AV node causes the first-degree AV block. **Right panel**, The PR interval is 230 milliseconds (PA = 39 msec; A-H = 100 msec; H-V = 95 msec) during a left bundle branch block. The conduction delay in the His-Purkinje system is causing the first-degree AV block. BAE = bipolar atrial electrogram; BEE = bipolar esophageal electrogram; BHE = bipolar His electrogram.

Second-Degree Atrioventricular Block

Blocking of some atrial impulses conducted to the ventricle at a time when physiologic interference is not involved constitutes second-degree AV block (Figs. 37-44 and 37-45; Fig. e37-12). The nonconducted P wave can be intermittent or frequent, occur at regular or irregular intervals, and be preceded by fixed or lengthening PR intervals. A distinguishing feature is that conducted P waves relate to the QRS complex with recurring PR intervals; that is, the association of P with QRS is not random. Electrocardiographically, typical type I second-degree AV block is characterized by progressive PR prolongation culminating in a nonconducted P wave (see Fig. e37-12), whereas in type II second-degree AV block, the PR interval remains constant before the blocked P wave (Fig. 37-46B). In both cases the AV block is intermittent and generally repetitive and can block several P waves in a row. Frequently, the eponyms Mobitz type I and Mobitz type II are applied to the two types of block, whereas Wenckebach block refers to type I block only. A Wenckebach block in the His-Purkinje system in a patient with a bundle branch block can resemble an AV nodal Wenckebach block very closely (see Fig. 37-46B).

Certain features of type I second-degree block deserve special emphasis because when actual conduction times are not apparent on the ECG—for example, during SA, junctional, or ventricular exit block (see Fig. 37-44)—a type I conduction disturbance can be difficult to recognize. During a typical type I block, the increment in conduction time is greatest in the second beat of the Wenckebach group, and the absolute increase in conduction time decreases progressively over subsequent beats. These two features serve to establish the characteristics of classic Wenckebach group beats: (1) the interval between successive beats progressively decreases, although the conduction time increases (but by a decreasing function); (2) the duration of the pause produced by the nonconducted impulse is less than twice the interval preceding the blocked impulse (which is usually the shortest interval); and (3) the cycle that follows the nonconducted beat (beginning the Wenckebach group) is longer than the cycle preceding the blocked impulse. Although much emphasis has been placed on this characteristic grouping of cycles, primarily to be able to diagnose a Wenckebach exit block, this typical grouping occurs in fewer than 50% of patients with a type I Wenckebach AV nodal block.

FIGURE 37-44 Typical 4:3 Wenckebach cycle. P waves (A tier) occur at a cycle length of 1000 milliseconds. The PR interval (AV tier) is 200 milliseconds for the first beat and generates a ventricular response (V tier). The PR interval increases by 100 milliseconds in the next complex, which results in an R-R interval of 1100 milliseconds (1000 + 100). The increment in the PR interval is only 50 milliseconds for the third cycle, and the PR interval becomes 350 milliseconds. The R-R interval shortens to 1050 milliseconds (1000 + 50). The next P wave is blocked, and an R-R interval is created that is less than twice the P-P interval by an amount equal to the increments in the PR interval. Thus the Wenckebach features explained in the text can be found in this diagram. If the increment in the PR interval of the last conducted complex increased rather than decreased (e.g., 150 msec rather than 50 msec), the last R-R interval before the block would increase (1150 msec) rather than decrease and thus become an example of an atypical Wenckebach cycle (see Fig. 37-39). If this were a Wenckebach exit block from the sinus node to the atrium, the sinus node cycle length (S) would be 1000 milliseconds, and the SA interval would increase from 200 to 300 to 350 milliseconds and culminate in a block. These events would be inapparent on a scalar ECG. However, the P-P interval on the ECG would shorten from 1100 to 1050 milliseconds, and finally, there would be a pause of 1850 milliseconds (A). If this rhythm were a junctional rhythm arising from the His bundle and conducting to the ventricle, the junctional rhythm cycle length would be 1000 milliseconds (H) and the H-V interval would progressively lengthen from 200 to 300 to 350 milliseconds, whereas the R-R interval would decrease from 1100 to 1050 milliseconds and then increase to 1850 milliseconds (V). The only clue to the Wenckebach exit block would be the changes in cycle length in the ventricular rhythm.

FIGURE e37-12 Unidirectional block. **Top**, During spontaneous sinus rhythm at a rate of 68 beats/min, 2:1 anterograde atrioventricular conduction occurs. **Bottom**, 1:1 retrograde conduction is seen during ventricular pacing at a rate of 70 beats/min. P waves are indicated by *arrowheads*.

FIGURE 37-45 A, Type I (Wenckebach) AV nodal block. During spontaneous sinus rhythm, progressive PR prolongation occurs and culminates in a nonconducted P wave. From the His bundle recording (HBE), it is apparent that the conduction delay and subsequent block occur within the AV node. Because the increment in conduction delay does not consistently decrease, the R-R intervals do not reflect the classic Wenckebach structure. **B**, Recorded 5 minutes after the intravenous administration of atropine, 0.6 mg. Atropine has had its predominant effect on sinus and junctional automaticity by this time, with little improvement in AV conduction. Consequently, more P waves are blocked, and AV dissociation, caused by a combination of AV block and an enhanced junctional discharge rate, is present. At 8 minutes (not shown), when atropine finally improved AV conduction, 1:1 AV conduction occurred. RA = right atrium.

FIGURE 37-46 Type II AV block. A, The sudden development of a His-Purkinje block is apparent. The A-H and H-V intervals remain constant, as does the PR interval. A left bundle branch block is present. **B**, Wenckebach AV block in the His-Purkinje system. The QRS complex exhibits a right bundle branch block morphology. However, note that the second QRS complex in the 3:2 conduction exhibits a slightly different contour from the first QRS complex, particularly in V1. This finding is the clue that the Wenckebach AV block might be in the His-Purkinje system. The H-V interval increases from 70 to 280 milliseconds, and then a block distal to the His bundle results. HBE = His bundle electrogram; HRA = high right atrium; RV = right ventricle.

Differences in these cycle-length patterns can result from changes in pacemaker rate (e.g., sinus arrhythmia), in neurogenic control of conduction, and in the increment of conduction delay. For example, if the PR increment in the last cycle increases, the R-R cycle of the last conducted beat can lengthen rather than shorten. In addition, because the last conducted beat is often at a critical state of conduction, it can become blocked and produce a 5:3 or 3:1 conduction ratio instead of a 5:4 or 3:2 ratio. During a 3:2 Wenckebach structure, the duration of the cycle that follows the nonconducted beat will be

the same as the duration of the cycle that precedes the nonconducted beat.

Although it has been suggested that type I and type II AV block are different manifestations of the same EP mechanism that differ only quantitatively in the size of the increments, clinical separation of second-degree AV block into types I and II serves a useful function, and in most cases the differentiation can be made easily and reliably from the surface ECG. Type II AV block often antedates the development of Adams-Stokes syncope and complete AV block, whereas type I AV block with a normal QRS complex is generally more benign and does not progress to more advanced forms of AV conduction disturbance. In older people, type I AV block with or without bundle branch block has been associated with a clinical picture similar to that seen in type II AV block.

In a patient with an acute myocardial infarction, type I AV block usually accompanies inferior infarction (perhaps more often if an RV infarction also occurs), is transient, and does not require temporary pacing, whereas type II AV block occurs in the setting of acute anterior myocardial infarction, can require temporary or permanent pacing, and is associated with a high rate of mortality, generally as a result of pump failure. A high degree of AV block can occur in patients with acute inferior myocardial infarction and is associated with more myocardial damage and a higher mortality rate than in those without AV block.

Although type I conduction disturbance is ubiquitous and can occur in any cardiac tissue in vivo as well as in vitro, the site of block for the usual forms of second-degree AV block can generally be determined from the surface ECG with sufficient reliability to permit clinical decisions without requiring invasive EP studies. Type I AV block with a normal QRS complex almost always takes place at the level of the AV node, proximal to the His bundle. An exception is the uncommon patient with type I intrahisian block. Type II AV block, particularly in association with a bundle branch block, is localized to the His-Purkinje system. Type I AV block in a patient with a bundle branch block can be caused by a block in the AV node or in the His-Purkinje system. Type II AV block in a patient with a normal QRS complex can be caused by an intrahisian AV block, but the block is likely to be a type I AV nodal block, which exhibits small increments in AV conduction time.

Differentiation of Type I from Type II Atrioventricular Block

The preceding generalizations encompass most patients with second-degree AV block. However, certain caveats must be heeded to avoid misdiagnosis because of subtle electrocardiographic changes or exceptions.

1. A 2:1 AV block can be a form of type I or type II AV block (Fig. 37-47). If the QRS complex is normal, the block is more likely to be type I and located in the AV node, and one should search for transition of the 2:1 block to a 3:2 block, during which the PR interval lengthens in the second cardiac cycle. If a bundle branch block is present, the block can be located in the AV node or His-Purkinje system.
2. AV block can occur simultaneously at two or more levels and cause difficulty in distinguishing between types I and II.
3. If the atrial rate varies, it can alter conduction times and cause a type I AV block to stimulate a type II block or change a type II AV block into type I. For example, if the shortest atrial cycle length

- that has just achieved 1:1 AV nodal conduction at a constant PR interval is decreased by as little as 10 or 20 milliseconds, the P wave of the shortened cycle can block conduction at the level of the AV node without an apparent increase in the antecedent PR interval. An apparent type II AV block in the His-Purkinje system can be converted to type I in the His-Purkinje system in some patients by increasing the atrial rate.
4. Concealed premature His depolarizations can create electrocardiographic patterns that simulate those of type I or II AV block.
 5. Abrupt transient alterations in autonomic tone can cause sudden block of one or more P waves without altering the PR interval of the conducted P wave before or after the block. Thus, an apparent type II AV block would be produced at the AV node. Clinically, a burst of vagal tone usually lengthens the P-P interval, as well as produces an AV block.
 6. The response of the AV block to autonomic changes, either spontaneous or induced, to distinguish type I from type II AV block can be misleading. Although vagal stimulation generally increases and vagolytic agents decrease the extent of type I AV block, such conclusions are based on the assumption that the intervention acts primarily on the AV node and fail to consider rate changes. For example, atropine can minimally improve conduction in the AV node and markedly increase the sinus rate, which results in an increase in AV nodal conduction time and the degree of AV block as a result of the faster atrial rate (see Fig. 37-45B). Conversely, if an increase in vagal tone minimally prolongs AV conduction time but greatly slows the heart rate, the net effect on type I AV block may be to improve conduction. In general, however, carotid sinus massage improves and atropine worsens AV conduction in patients with His-Purkinje block, whereas the opposite results are to be expected in patients with AV nodal block. Similarly, exercise or isoproterenol is likely to increase the sinus rate and improve AV nodal block but worsen His-Purkinje block. These interventions can help differentiate the site of block without invasive study, although damaged His-Purkinje tissue may be influenced by changes in autonomic tone.
 7. During type I AV block with high ratios of conducted beats, the increment in PR interval can be quite small and suggest a type II AV block if only the last few PR intervals before the blocked P wave

are measured. Comparing the PR interval of the first beat in the long Wenckebach cycle with that of the beats immediately preceding the blocked P wave readily reveals the increment in AV conduction.

8. The classic AV Wenckebach structure depends on a stable atrial rate and a maximal increment in AV conduction time for the second PR interval of the Wenckebach cycle along with a progressive decrease in subsequent beats. Unstable or unusual alterations in the increment of AV conduction time or in the atrial rate, often seen with long Wenckebach cycles, result in atypical forms of type I AV block in which the last R-R interval can lengthen because the PR increment increases; such alterations are common.
9. Finally, the PR interval on the scalar ECG is made up of conduction through the atrium, AV node, and His-Purkinje system. An increment in H-V conduction, for example, can be masked on the scalar ECG by a reduction in the A-H interval, and the resulting PR interval will not reflect the entire increment in His-Purkinje conduction time. Very long PR intervals (200 msec) are more likely to result from AV nodal conduction delay (and block), with or without concomitant His-Purkinje conduction delay, although an H-V interval of 390 milliseconds is possible.

First-degree and type I second-degree AV block can occur in normal healthy children, and a Wenckebach AV block can be a normal phenomenon in well-trained athletes, as noted earlier, probably related to an increase in resting vagal tone. On occasion, progressive worsening of the Wenckebach AV conduction disorder can result and the athlete becomes symptomatic and has to decondition. In patients who have chronic second-degree AV nodal block (proximal to the His bundle) without structural heart disease, the course is relatively benign (except in older age groups), whereas in those with structural heart disease, the prognosis is poor and related to the underlying heart disease.

Third-Degree (Complete) Atrioventricular Block

Third-degree or complete AV block occurs when no atrial activity is conducted to the ventricles and therefore the atria and ventricles are controlled by independent pacemakers. Thus, complete AV block is one type of complete AV dissociation. The atrial pacemaker can be sinus or ectopic (tachycardia, flutter, or fibrillation) or can result from an AV junctional focus occurring above the block with retrograde atrial conduction. The ventricular focus is usually located just below the region of the block, which can be above or below the His bundle bifurcation. Sites of ventricular pacemaker activity that are in or closer to the His bundle appear to be more stable and can produce a faster escape rate than can those located more distally in the ventricular conduction system. The ventricular rate in acquired complete heart block is less than 40 beats/minute but can be faster with congenital complete AV block. The ventricular rhythm, usually regular, can vary in response to PVCs, a shift in the pacemaker site, an irregularly discharging pacemaker focus, or autonomic influences.

Complete AV block can result from a block at the level of the AV node (usually congenital; Fig. 37-48), within the bundle of His, or distal to it in the Purkinje system (usually acquired; Fig. e37-13).⁴⁹ Block proximal to the His bundle generally exhibits normal QRS complexes and rates of 40 to 60 beats/minute because the escape focus that controls the ventricle arises in or near the His bundle. In complete AV nodal block, the P wave is not followed by a His deflection, but each ventricular complex is preceded by a His deflection (see Fig. 37-48). His bundle recording can be useful to differentiate AV nodal from intrahisian block because the latter may carry a more serious prognosis than the former. Intrahisian block is recognized infrequently

FIGURE 37-47 A 2:1 AV block proximal and distal to the His bundle deflection in two different patients. **A**, A 2:1 AV block seen on the scalar ECG occurs distal to the His bundle recording site in a patient with a right bundle branch block and anterior hemiblock. The A-H interval (150 msec) and H-V interval (80 msec) are both prolonged. **B**, A 2:1 AV block proximal to the bundle of His in a patient with a normal QRS complex. The A-H interval (75 msec) and the H-V interval (30 msec) remain constant and normal. BAE = bipolar atrial electrogram; BEE = bipolar esophageal electrogram; BHE = bipolar His electrogram.

FIGURE e37-13 Complete anterograde AV block with retrograde VA conduction. All the sinus P waves are blocked distal to the His bundle, consistent with acquired complete AV block. The ventricles escape at a cycle length of approximately 1800 milliseconds (33 beats/min) and are not preceded by His-bundle activation. The ventricular escape rhythm produces a QRS contour with left-axis deviation and a right bundle branch block, possibly caused by impulse origin in the posterior fascicle of the left bundle branch. Of interest is the fact that the second ventricular escape beat conducts retrogradely through His (H) and to the atrium (note the low-high atrial activation sequence and the negative P wave in leads II and III). The first ventricular complex does not conduct retrogradely, probably because the His bundle is still refractory from the immediately preceding atrial impulse. HBE = His bundle electrogram; HRA = high right atrium; RV = right ventricle.

FIGURE 37-48 Congenital third-degree AV block. **A**, A complete AV nodal block is apparent. No P wave is followed by a His bundle potential, whereas each ventricular depolarization is preceded by a His bundle potential. **B**, Atrial pacing (cycle length of 500 msec) fails to alter the cycle length of the functional rhythm. Still, no P wave is followed by a His bundle potential. **C**, After 30 seconds of ventricular pacing (cycle length of 700 msec), suppression of the junctional focus results for almost 7 seconds (overdrive suppression of automaticity). HBE = His bundle electrogram; RA = right atrium; RV = right ventricle.

without invasive studies. In patients with AV nodal block, atropine generally speeds both the atrial and ventricular rates. Exercise can reduce the extent of AV nodal block. Acquired complete AV block occurs most commonly distal to the bundle of His because of trifascicular conduction disturbance. Each P wave is followed by a His deflection, and the ventricular escape complexes are not preceded by a His deflection (see Fig. e37-13). The QRS complex is abnormal, and the ventricular rate is generally less than 40 beats/minute. A hereditary form caused by degeneration of the His bundle and bundle branches has been linked to the *SCN5A* gene, which is also responsible for LQT3 (see Chapter 32).

Paroxysmal AV block⁵⁰ can in some cases be caused by hyper-responsiveness of the AV node to vagotonic reflexes. Surgery, electrolyte disturbances, myoendocarditis, tumors, Chagas disease, rheumatoid nodules, calcific aortic stenosis, myxedema, polymyositis, infiltrative processes (e.g., amyloidosis, sarcoidosis, scleroderma), and an almost endless assortment of common and unusual conditions can produce AV block. In adults, rapid rates can sometimes be followed by block (called tachycardia-dependent AV block), which is thought to be due to a phase 3 block (block caused by incomplete action potential recovery), postrepolarization refractoriness, and concealed conduction in the AV node.⁵¹ Less common than tachycardia-dependent AV block, pause-dependent paroxysmal AV block can also occur; it results in AV block after a pause or during relative bradycardia and thus can be difficult to distinguish from vagal AV block. This form of AV block is often referred to as a phase 4 block because it is thought that spontaneous depolarizations during the resting phase of the action potential result in an inability to depolarize, although other mechanisms may also play a role.

In children the most common cause of AV block is congenital (see Chapter 62). In such circumstances the AV block can be an isolated

finding or be associated with other lesions. Neonatal autoimmune disease, from maternal antibodies crossing the placenta, account for most cases of heart block in utero or in the immediate neonatal period, but only for rare cases of congenital heart block occurring after this period. Anatomic disruption between the atrial musculature and peripheral parts of the conduction system and nodoventricular discontinuity are two common histologic findings. Children are most often asymptomatic; however, in some children, symptoms requiring pacemaker implantation develop. Mortality from congenital AV block is highest in the neonatal period, is much lower during childhood and adolescence, and increases slowly later in life. Adams-Stokes attacks can occur in patients with congenital heart block at any age. It is difficult to predict the prognosis in an individual patient. A persistent heart rate at rest of 50 beats/minute or less correlates with the incidence of syncope, and extreme bradycardia can contribute to the frequency of Adams-Stokes attacks in children with congenital complete AV block. The site of block may not distinguish symptomatic children who have congenital or surgically induced complete heart block from those without symptoms. Prolonged recovery times of escape foci after rapid pacing (see Fig. 37-48C), slow heart rates on 24-hour electrocardiographic recordings, and the occurrence of paroxysmal tachycardias may be factors predisposing to the development of symptoms.

Clinical Features

Many of the signs of AV block are evident at the bedside. First-degree AV block can be recognized by a long *a* to *c* wave interval in the jugular venous pulse and by diminished intensity of the first heart sound as the PR interval lengthens. In type I second-degree AV block, the heart rate may increase imperceptibly with gradually diminishing intensity of the first heart sound; widening of the *a* to *c* interval, terminated by a pause; and an *a* wave not followed by a *v* wave. Intermittent ventricular pauses and *a* waves in the neck not followed by *v* waves characterize type II AV block. The first heart sound maintains a constant intensity. In complete AV block, the findings are the same as those in AV dissociation (see later).

Significant clinical manifestations of first- and second-degree AV block usually consist of palpitations or subjective feelings of the heart “missing a beat.” Persistent 2:1 AV block can produce symptoms of chronic bradycardia. Complete AV block can be accompanied by signs and symptoms of reduced cardiac output, syncope or presyncope, angina, or palpitations from ventricular tachyarrhythmias. It can occur in twins.

Management

For patients with transient or paroxysmal AV block and presyncope or syncope, the diagnosis can be elusive. Ambulatory monitoring (Holter or external loop recorders) can be useful, but monitoring for longer periods may be necessary, with extended (>3 weeks) Holter or external loop recorders being required. Longer periods of recording require an implantable loop recorder to establish the diagnosis. In patients with presyncope or syncope, one should suspect intermittent infra-His block in those with bundle branch block or an intraventricular conduction defect. An EP study to thoroughly evaluate AV conduction (including infusion of isoproterenol and/or procainamide) may be warranted to make the diagnosis, particularly in those with severe symptoms (see Chapter 34).

Drugs cannot be relied on to increase the heart rate for more than several hours to several days in patients with symptomatic heart block without producing significant side effects. Therefore, temporary or permanent pacemaker insertion is indicated for patients with symptomatic bradyarrhythmias. For short-term therapy, when the block is likely to be evanescent but still requires treatment or until adequate pacing therapy can be established, vagolytic agents such as atropine are useful for patients who have AV nodal disturbances, whereas catecholamines such as isoproterenol can be used transiently to treat patients who have heart block at any site (see Sinus Bradycardia). Isoproterenol should be used with extreme caution or not at all in patients with acute myocardial infarction. The use of transcutaneous or temporary transvenous pacing is preferable. For

symptomatic AV block or high-grade AV block (e.g., infrahisian, type II AV block, third-degree heart block not caused by congenital AV block), permanent pacemaker placement is the treatment of choice.

Classification

As the term indicates, dissociated or independent beating of the atria and ventricles defines AV dissociation. AV dissociation is never a primary disturbance of rhythm but is a “symptom” of an underlying rhythm disturbance produced by one of three causes or a combination of causes (**Fig. e37-14**) that prevent the normal transmission of impulses from atrium to ventricle:

1. Slowing of the dominant pacemaker of the heart (usually the sinus node), which allows escape of a subsidiary or latent pacemaker. AV dissociation by default of the primary pacemaker to a subsidiary one in this manner is often a normal phenomenon. It may occur during sinus arrhythmia or sinus bradycardia and permit an independent AV junctional rhythm to arise (see **Fig. 37-39A**).
2. Acceleration of a latent pacemaker, for example, a tachycardia in which the atria are not required and that usurps control of the ventricles. An abnormally enhanced discharge rate of a usually slower subsidiary pacemaker is pathologic and commonly occurs during nonparoxysmal AV junctional tachycardia or VT without retrograde atrial capture (**Fig. e37-15**; also see **Fig. 37-27**).
3. A block, generally at the AV junction, that prevents impulses formed at a normal rate in a dominant pacemaker from reaching the ventricles and allows the ventricles to beat under the control of a subsidiary pacemaker. Junctional or ventricular escape rhythm during AV block, without retrograde atrial capture, is a common example in which block gives rise to AV dissociation. Complete AV block is not synonymous with complete AV dissociation. Patients who have complete AV block have complete AV dissociation, but patients who have complete AV dissociation may or may not have complete AV block (see **Figs. 37-48** and **e37-13**).
4. A combination of causes, for example, when excess digitalis results in the production of nonparoxysmal AV junctional tachycardia associated with SA or AV block.

Mechanisms

With this classification in mind, it is important to emphasize that AV dissociation is not a diagnosis and is used in a manner similar to jaundice or fever. One must state that “AV dissociation is present and is caused by...” and then give the cause. An accelerated rate of a slower, normally subsidiary pacemaker and a slower rate of a faster, normally dominant pacemaker that prevents conduction because of physiologic collision and mutual extinction of opposing wave fronts (interference) or the manifestations of AV block are the basic disturbances producing AV dissociation. The atria in all these cases beat independently from the ventricles, under control of the sinus node or ectopic atrial or AV junctional pacemakers, and can exhibit any type of supraventricular rhythm. If a single pacemaker establishes control of both the atria and ventricles for one beat (capture) or a series of beats (e.g., sinus rhythm, AV junctional rhythm with retrograde atrial capture [see **Figs. e37-12** and **e37-13**], VT with retrograde atrial

capture), AV dissociation is abolished for that period. Conversely, as stated earlier, whenever the atria and ventricles fail to respond to a single impulse for one beat (PVC without retrograde capture of the atrium) or a series of beats (VT without retrograde atrial capture), AV dissociation exists for that period. Interruption of AV dissociation by one or a series of beats under the control of one pacemaker, anterogradely or retrogradely, indicates that the AV dissociation is incomplete. Complete or incomplete dissociation can also occur in association with all forms of AV block. Commonly, when AV dissociation occurs as a result of AV block, the atrial rate exceeds the ventricular rate. For example, a subsidiary pacemaker with a rate of 40 beats/minute can escape in the presence of a 2:1 AV block when the atrial rate is 78 beats/minute. If the AV block is bidirectional, AV dissociation results.

Electrocardiographic and Clinical Features

The ECG demonstrates the independence of P waves and QRS complexes. P wave morphology depends on the rhythm controlling the atria—sinus, atrial tachycardia, junctional, flutter, or fibrillation. During complete AV dissociation, both the QRS complex and the P waves appear to be regularly spaced without a fixed temporal relationship to each other. When the dissociation is incomplete, a QRS complex with a supraventricular contour occurs early and is preceded by a P wave at a PR interval exceeding 0.12 second and within a conductible range. This combination indicates ventricular capture by the supraventricular focus. Similarly, a premature P wave with retrograde morphology and a conductible RP interval may indicate retrograde atrial capture by the subsidiary focus.

Physical findings include a variable intensity of the first heart sound as the PR interval changes, atrial sounds, and *a* waves in the jugular venous pulse lacking a consistent relationship to ventricular contraction. Intermittent large (cannon) *a* waves may be seen in the jugular venous pulse when atrial and ventricular contractions occur simultaneously. The second heart sound can split normally or paradoxically, depending on the manner of ventricular activation. A premature beat representing ventricular capture can interrupt a regular heart rhythm. When the ventricular rate exceeds the atrial rate, a cyclical increase in intensity of the first heart sound is produced as the PR interval shortens, climaxed by a very loud sound (bruit de canon). This intense sound is followed by a sudden reduction in intensity of the first heart sound and the appearance of giant *a* waves as the PR interval shortens and P waves “march through” the cardiac cycle.

Management

Management is directed toward the underlying heart disease and precipitating cause. The individual components producing the AV dissociation, not the AV dissociation per se, determine the specific type of antiarrhythmic approach.

FIGURE e37-14 Diagrammatic illustration of the four causes of AV dissociation. A sinus bradycardia allowing escape of an AV junctional rhythm that does not capture the atria retrogradely illustrates cause I; intermittent sinus captures occur (third P wave) and produce incomplete AV dissociation. For cause II, VT without retrograde atrial capture produces complete AV dissociation (see Figs. 37-27 and e37-15). As the third cause, complete AV block with a ventricular escape rhythm is diagrammed (see Figs. 39-48 and 39-e13). In the **bottom panel**, the combination of causes II and III is shown, which represents a nonparoxysmal AV junctional tachycardia and some degree of AV block.

FIGURE e37-15 Nonparoxysmal AV junctional tachycardia in a healthy young adult. **Top**, This tachycardia occurs at a fairly regular interval (W-shaped complexes) and is interrupted intermittently with sinus captures that produce functional right and left bundle branch blocks. **Middle**, Two P waves are indicated by *arrowheads*. The junctional discharge rate is approximately 120 beats/min (cycle length = 500 msec) and the rhythm is irregular, sometimes shortened by sinus captures or delayed by concealed conduction that resets and displaces the junctional focus. **Bottom**, Carotid sinus massage slows both the junctional and the sinus discharge rates.

ELECTROCARDIOGRAPHIC FEATURES

Atrial fibrillation (AF) is a supraventricular arrhythmia characterized electrocardiographically by low-amplitude baseline oscillations (fibrillatory or f waves) and an irregularly irregular ventricular rhythm. The f waves have a rate of 300 to 600 beats/min and are variable in amplitude, shape, and timing. In contrast, flutter waves have a rate of 250 to 350 beats/min and are constant in timing and morphology (**Fig. 38-1**). In lead V₁, f waves sometimes appear uniform and can mimic flutter waves (**Fig. 38-2**). The distinguishing feature from atrial flutter is the absence of uniform and regular atrial activity in other leads of the electrocardiogram. In some patients, f waves are very small and not perceptible on the electrocardiogram. In such patients the diagnosis of AF is based on the irregularly irregular ventricular rhythm (**Fig. 38-3**).

The ventricular rate during AF in the absence of negative dromotropic agents is typically 100 to 160 beats/min. In patients with Wolff-Parkinson-White syndrome, the ventricular rate during AF can exceed 250 beats/min because of conduction over the accessory pathway (see **Chapter 37**). When the ventricular rate during AF is very rapid (>170 beats/min), the degree of irregularity is attenuated and the rhythm can seem regular (**Fig. 38-4**).

The ventricular rhythm can be regular during AF in patients with a ventricular pacemaker who are fully paced and when a third-degree atrioventricular (AV) block with a regular escape rhythm is present (**Fig. 38-5**). In these cases the diagnosis of AF is based on the presence of f waves. When there is a third-degree AV block with a junctional escape, a Wenckebach exit block in the AV junction (as can occur during digitalis toxicity) results in a regularly irregular ventricular rate (see **Chapters 34 and 37**).

CLASSIFICATION OF ATRIAL FIBRILLATION

AF that terminates spontaneously within 7 days is termed *paroxysmal*, and AF present continuously for more than 7 days is called *persistent*.

AF that is persistent for longer than 1 year is termed *longstanding*, whereas longstanding AF refractory to cardioversion is termed *permanent*. However, “permanent AF” is not necessarily permanent in the literal sense because it may be eliminated successfully by surgical or catheter ablation.

Some patients with paroxysmal AF can occasionally have episodes that are persistent, and vice versa. The predominant form of AF determines how it should be categorized.

A confounding factor in the classification of AF is cardioversion and antiarrhythmic drug therapy. For example, if a patient undergoes transthoracic cardioversion 24 hours after the onset of AF, it is unknown whether the AF would have persisted for more than 7 days. Furthermore, antiarrhythmic drug therapy may change persistent AF into paroxysmal AF. It is generally thought that the classification of AF should not be altered on the basis of the effects of electrical cardioversion or antiarrhythmic drug therapy.

Lone AF refers to AF that occurs in patients younger than 60 years who do not have hypertension or any evidence of structural heart disease. This designation is clinically relevant because patients with lone AF are at lower risk for thromboembolic complications, thus eliminating the necessity for anticoagulation with warfarin. In addition, the absence of structural heart disease allows the safe use of rhythm-control drugs such as flecainide in patients with lone AF.

Paroxysmal AF can also be classified clinically on the basis of the autonomic setting in which it most often occurs. Approximately 25% of patients with paroxysmal AF have vagotonic AF, in which AF is initiated in the setting of high vagal tone, typically in the evening when the patient is relaxing or during sleep. Drugs that have a vagotonic effect (such as digitalis) can aggravate vagotonic AF, and drugs that have a vagolytic effect (such as disopyramide) may be particularly appropriate for prophylactic therapy. Adrenergic AF occurs in approximately 10% to 15% of patients with paroxysmal AF in the setting of high sympathetic tone, for example, during strenuous exertion. In patients with adrenergic AF, beta blockers not only provide rate control but can also prevent the onset of AF. Most patients have a mixed or random form of paroxysmal AF, with no consistent pattern of onset.

FIGURE 38-1 Comparison of the f waves of AF (**top panel**) and the flutter waves of atrial flutter (**bottom panel**). Note that f waves are variable in rate, shape, and amplitude whereas flutter waves are constant in rate and all aspects of morphology. Shown are leads V₁, II, and V₅.

FIGURE 38-2 Example of AF with prominent f waves in V₁ that mimic atrial flutter waves. Note that typical f waves are present in leads II and V₅, thereby establishing the diagnosis of AF.

FIGURE 38-3 A 12-lead electrocardiogram of AF in which f waves are not discernible. The irregularly irregular ventricular rate indicates that this is AF and not a junctional rhythm.

FIGURE 38-4 Recording of AF with a rapid ventricular rate of 160 beats/min. Shown are leads V₁, II, and V₅. On quick review there may appear to be a regular rate consistent with paroxysmal supraventricular tachycardia. On closer inspection, however, it is clear that the rate is irregularly irregular.

FIGURE 38-5 Atrial fibrillation with complete heart block and a regular junctional rhythm at a rate of 45 beats/min.

EPIDEMIOLOGY OF ATRIAL FIBRILLATION

AF is the most common arrhythmia treated in clinical practice and the most common arrhythmia for which patients are hospitalized; approximately 33% of arrhythmia-related hospitalizations are for AF. AF is associated with an approximately fivefold increase in the risk for stroke and a twofold increase in the risk for all-cause mortality.¹ AF is also associated with the development of heart failure.

Estimates of the actual number of individuals with AF in the United States range between 2.3 and 5 million in most studies. The incidence of AF is age and sex related and ranges from 0.1% per year before the age of 40 years to higher than 1.5% per year in women and higher than 2% per year in men older than 80 years. Heart failure, aortic and mitral valve disease, left atrial enlargement, hypertension, and advanced age are independent risk factors for the development of AF, as are obesity and obstructive sleep apnea² (see Chapter 75). Another risk factor is psoriasis, which when severe, triples the risk for AF in patients younger than 50 years.³

A community-based cohort study in Olmstead County, Minnesota, reported that the age-adjusted incidence of AF per 1000 person-years

increased significantly between 1980 and 2000 from 4.4 to 5.4 in men and from 2.4 to 2.8 in women.⁴ There was a relative increase of 0.6% per year in the age-adjusted incidence of AF. An increase in obesity accounted for 60% of the age-adjusted increase in AF incidence. The number of patients with AF in the United States was estimated to be 3.2 million in 1980 and 5.1 million in 2000 and was projected to be 12.1 to 15.9 million in 2050, all of which are higher than previous estimates.

MECHANISMS OF ATRIAL FIBRILLATION

The mechanisms responsible for AF are complex. Triggering events may differ from maintenance mechanisms. In addition, the clinical phenotypes of paroxysmal, persistent, and longstanding persistent AF have different electrophysiologic characteristics because of remodeling and different clinical modulators that affect the substrate, such as heart failure, atrial stretch and ischemia, sympathovagal influences, inflammation, and fibrosis.

There are probably two electrophysiologic mechanisms of AF: one or more automatic, triggered, or microreentrant foci, so-called

drivers, which fire at rapid rates and cause fibrillation-like activity, and multiple reentrant circuits meandering throughout the atria that annihilate and reform wavelets, thereby perpetuating the fibrillation. In many studies the left atrium contains the site of dominant frequency discharge, with a left-to-right gradient. Both mechanisms may be present simultaneously. In a recent study, computational maps were obtained in patients by signal processing of multiple electrograms recorded simultaneously during AF.⁵ This technique can reveal electrical rotors and focal sources. A mean of 2.1 sources was found in 97% of 101 patients, with 70% being rotors and 30% being focal sources.

Rapid discharges from the pulmonary veins are the most common triggers of AF and may also play a perpetuating role, more so in paroxysmal AF than in persistent AF. This is why pulmonary vein isolation is particularly effective for elimination of paroxysmal AF. In persistent AF, changes in the atrial substrate, including interstitial fibrosis, which contributes to slow, discontinuous, and anisotropic conduction, may give rise to complex fractionated atrial electrograms (CFAEs) and reentry. Therefore, pulmonary vein isolation is rarely sufficient to eliminate persistent AF, and additional ablation of the atrial substrate is usually necessary.

GENETIC FACTORS

Several mutations that are responsible for familial AF and that predispose to AF have been identified.⁶ These mutations cause a gain of function of repolarization potassium currents that results in shortening of atrial refractoriness and facilitation of atrial reentry. Multiple polymorphisms that are associated with AF that is idiopathic, are associated with structural heart disease, or occur postoperatively have also been identified.⁶ These polymorphisms are in genes that affect potassium and sodium channels, sarcoplipin, the renin-angiotensin system, connexin 40, endothelial nitric oxide synthase, and interleukin-10. The end results are changes in calcium handling, fibrosis, conduction, and inflammation that predispose to AF.

CAUSES OF ATRIAL FIBRILLATION

Most patients with AF have hypertension (usually with left ventricular hypertrophy; [see Chapters 43 and 44](#)) or some other form of structural heart disease. In addition to hypertensive heart disease, the most common cardiac abnormalities associated with AF are ischemic heart disease, mitral valve disease, hypertrophic cardiomyopathy, and dilated cardiomyopathy. Less common causes of AF are restrictive cardiomyopathies such as amyloidosis, constrictive pericarditis, and cardiac tumors. Severe pulmonary hypertension is often associated with AF.

Obesity and obstructive sleep apnea ([see Chapter 75](#)) are associated with each other, and both have been found to independently increase the risk for AF.² The data available suggest that atrial dilation and an increase in systemic inflammatory factors are responsible for the relationship between obesity and AF. Possible mechanisms of AF in patients with sleep apnea include hypoxia, surges in autonomic tone, and hypertension.

AF can be due to causes that are temporary or reversible. The most common temporary causes are excessive alcohol intake (holiday heart), open heart or thoracic surgery, myocardial infarction, pericarditis ([see Chapter 71](#)), myocarditis, and pulmonary embolism ([see Chapter 73](#)). The most common correctable cause is hyperthyroidism ([see Chapter 81](#)).

AF is sometimes induced by tachycardia. Patients with tachycardia-induced AF most often have AV nodal reentrant tachycardia or a tachycardia related to Wolff-Parkinson-White syndrome that degenerates into AF. If a patient with AF has a history of rapid and regular palpitations before the onset of irregular palpitations or has a Wolff-Parkinson-White electrocardiographic pattern, this should raise suspicion for tachycardia-induced AF. Treatment of the tachycardia that triggers the AF often but not always prevents recurrences of AF.

CLINICAL FEATURES

The symptoms of AF vary widely between patients and range from none to severe and functionally disabling. The most common symptoms of AF are palpitations, fatigue, dyspnea, effort intolerance, and lightheadedness. Polyuria can occur because of the release of atrial natriuretic hormone. Many patients with symptomatic paroxysmal AF also have asymptomatic episodes, and some patients with persistent AF have symptoms only intermittently, thus making it difficult to accurately assess the frequency and duration of AF on the basis of symptoms.

It is estimated that approximately 25% of patients with AF are asymptomatic, more commonly elderly patients and those with persistent AF. Such patients are sometimes erroneously classified as having asymptomatic AF despite the presence of fatigue or effort intolerance. Because fatigue is a nonspecific symptom, it may not be clearly due to persistent AF. “Diagnostic cardioversion” may be helpful by maintaining sinus rhythm for at least a few days to determine whether a patient feels better in sinus rhythm. This can provide a basis to pursue a rhythm-control versus rate-control strategy.

Syncope is an uncommon symptom of AF. It can be caused by a long sinus pause on termination of AF in a patient with sick sinus syndrome. Syncope can also occur during AF with a rapid ventricular rate either because of neurocardiogenic (vasodepressor) syncope that is triggered by the tachycardia or because of a severe drop in blood pressure secondary to a reduction in cardiac output.

Asymptomatic or minimally symptomatic AF patients are not prompted to seek medical care and can initially be seen with a thromboembolic complication such as stroke or the insidious onset of heart failure symptoms that eventually results in florid congestive heart failure.

The hallmark of AF on physical examination is an irregularly irregular pulse. Short R-R intervals during AF do not allow adequate time for left ventricular diastolic filling, which results in a low stroke volume and the absence of palpable peripheral pulse. This leads to a “pulse deficit,” during which the peripheral pulse is not as rapid as the apical rate. Other manifestations of AF on physical examination are irregular jugular venous pulsations and variable intensity of the first heart sound.

DIAGNOSTIC EVALUATION

In a patient who describes irregular or rapid palpitations suggestive of paroxysmal AF, ambulatory monitoring is useful to document whether AF is responsible for the symptoms. If the symptoms occur on a daily basis, a 24-hour Holter recording is appropriate. However, extended monitoring for 2 to 4 weeks with an event monitor or by mobile cardiac outpatient telemetry is appropriate for patients whose symptoms are sporadic ([see Chapter 34](#)).

The history should be directed at determination of the type and severity of symptoms, the first onset of AF, whether the AF is paroxysmal or persistent, triggers for AF, whether the episodes are random or occur at particular times (such as during sleep), and the frequency and duration of episodes. When it is unclear from the history, 2 to 4 weeks of ambulatory monitoring with an autotrigger event monitor or by mobile cardiac outpatient telemetry is useful to determine whether the AF is paroxysmal or persistent and to quantitate the AF burden in patients with paroxysmal AF. The history also should be directed at identification of potentially correctable causes (e.g., hyperthyroidism, excessive alcohol intake), structural heart disease, and comorbid conditions.

Laboratory testing should include thyroid function tests, liver function tests, and renal function tests. Echocardiography is always appropriate to evaluate atrial size and left ventricular function and to look for left ventricular hypertrophy, congenital heart disease ([see Chapter 62](#)), and valvular heart disease. Chest radiography is appropriate if the history or findings on physical examination are suggestive of pulmonary disease ([see Chapter 15](#)). A stress test is appropriate for evaluation of ischemic heart disease in at-risk patients ([see Chapter 13](#)).

PREVENTION OF THROMBOEMBOLIC COMPLICATIONS

Risk Stratification

A major goal of therapy in patients with AF is to prevent thromboembolic complications such as stroke. It is well established that warfarin is more effective than aspirin for prevention of thromboembolic complications.⁷ However, because of the risk for hemorrhage during warfarin therapy, its use should be limited to patients whose risk for thromboembolic complications is greater than their risk for hemorrhage. Therefore, it is useful to risk-stratify patients with AF to identify appropriate candidates for warfarin therapy.

The strongest predictors of ischemic stroke and systemic thromboembolism are a history of stroke or a transient ischemic episode and mitral stenosis. When patients with AF and a previous ischemic stroke are treated with aspirin, the risk for another stroke is very high, in the range of 10% to 12% per year. At the other end of the risk spectrum are patients with lone AF, whose cumulative 15-year risk for stroke was reported to be in the range of 1% to 2%. Aside from previous stroke, the best-established risk factors for stroke in patients with nonvalvular AF are diabetes (relative risk, 1.7), hypertension (relative risk, 1.6), heart failure (relative risk, 1.4), and age 70 years or older (relative risk, 1.4 per decade).⁸

A simple clinical scheme to risk-stratify patients on the basis of major risk factors is the CHADS₂ (cardiac failure, hypertension, age, diabetes, stroke) score. Each of the first four risk factors is worth 1 point, and a previous stroke or transient ischemic event is worth 2 points. There is a direct relationship between the CHADS₂ score and the annual risk for stroke in the absence of aspirin or warfarin therapy. The clinical value of the CHADS₂ score lies in its simplicity and predictive value. However, recent studies have demonstrated that the CHA₂DS₂-VASc score more accurately discriminates low-risk from intermediate-risk patients.⁹

In this risk score system, cardiac failure, hypertension, diabetes, vascular disease, 65 to 74 years of age, and female sex are worth 1 point each, whereas age 75 years or older and previous stroke or transient ischemic event are worth 2 points. The annual risk for stroke is zero or close to zero when the CHA₂DS₂-VASc score is 0, as opposed to approximately 2% when the CHADS₂ score is 0.¹⁰ A score of 1 is associated with an annual stroke risk of approximately 3% with the CHADS₂ score versus 0.7% with the CHA₂DS₂-VASc score (Fig. 38-6).

A large-scale study demonstrated that renal failure is also an independent risk factor for stroke in patients with AF.¹¹ The relative risk for a thromboembolic event in the absence of anticoagulation was 1.4 in patients with an estimated glomerular filtration rate lower than 45 mL/min/1.73 m². The predictive strength of this degree of renal failure for a thromboembolic event appears to be equivalent to that

of heart failure and advanced age. Therefore, it may be appropriate to take renal failure into account in evaluating the risk profile of a patient with AF.

By definition, the burden of AF is greater in patients with persistent AF than in those with paroxysmal AF. It may seem reasonable to assume that the risk for stroke is lower in patients with occasional episodes of self-limited AF than in those with AF continuously. However, the data available in fact indicate that the risk for thromboembolic complications is the same in patients with paroxysmal and persistent AF. Even 15 minutes of AF may be long enough to result in local cardiac platelet activation and endothelial dysfunction, which predispose to thrombus formation during an acute episode of AF.¹² Therefore, the type of AF should not be taken into account in risk-stratifying AF patients for thromboembolic risk.

Modern-day dual-chamber pacemakers and implantable cardioverter-defibrillators (ICDs) are capable of detecting short episodes of asymptomatic AF that would otherwise not have been detected clinically. In a recent multicenter prospective study, subclinical atrial tachyarrhythmias (atrial rate >190 beats/min for >6 minutes) were detected by device interrogation in 10.1% of patients 65 years or older with hypertension and no history of AF who received a pacemaker or ICD.¹³ Subclinical atrial tachyarrhythmias were independently associated with a 2.5-fold increase in the risk for stroke.

An important consideration in patients treated with an oral anticoagulant is the risk for bleeding. Several risk stratification scoring systems have been developed to assess a patient's susceptibility to hemorrhagic complications. The scoring system with the best balance of simplicity and accuracy is the HAS-BLED score.¹⁴ The components of this score are hypertension, abnormal renal or liver function, stroke, bleeding history or predisposition, labile international normalized ratio (INR), older age (>75 years), and concomitant drug (antiplatelet agent or nonsteroidal anti-inflammatory drug) or alcohol use. Each of these components is worth 1 point. As the score increases from 0 to the maximum of 9, there is a stepwise increase in the risk for bleeding in patients treated with warfarin. For example, in one study the annual rate of major bleeding was 1.1% in patients with a HAS-BLED score of 0, 3.7% with a score of 3, and 12.5% with a score of 5.¹⁵

In two large-scale cohort studies totaling 132,372 patients¹⁶ and 170,292 patients¹⁷ with nonvalvular AF, the CHA₂DS₂-VASc and HAS-BLED scores were calculated for each patient. The net clinical benefit of warfarin was defined as the number of strokes while not taking warfarin minus the number of intracranial bleeding episodes while taking warfarin. In both studies, warfarin was associated with a net clinical benefit except when the CHA₂DS₂-VASc score was 0. In patients with a CHA₂DS₂-VASc score of 1 or higher, the risk for stroke in the absence of warfarin exceeded the number of bleeding complications during treatment with warfarin.

The results of these large cohort studies notwithstanding, the decision to institute anticoagulation in a patient in clinical practice should be individualized. At times it may be appropriate to not initiate anticoagulation in a patient with a CHA₂DS₂-VASc score of 1 or higher. For example, the annual risk for stroke in a patient with a CHA₂DS₂-VASc score of 2 is approximately 2%, which usually justifies the use of warfarin. However, if that patient has a HAS-BLED score of 5 or higher, which is associated with an annual risk for major bleeding of 12% or higher, it would be imprudent to treat that patient with warfarin.

It should be noted that the HAS-BLED score was developed and validated in patients in whom warfarin was used for anticoagulation. Except for labile INR, it is likely that the components of the HAS-BLED score also apply to patients in whom a direct thrombin inhibitor or factor Xa inhibitor is used for anticoagulation. However, the predictive value of the HAS-BLED score in patients treated with one of the newer antithrombotic agents has not yet been determined.

FIGURE 38-6 Annual risk for stroke (percent risk per year) based on the CHADS₂ and CHA₂DS₂-VASc scores. (Based on data from Lip GY: Implications of the CHA₂DS₂-VASc and HAS-BLED scores for thromboprophylaxis in atrial fibrillation. *Am J Med* 124:111, 2011.)

Aspirin and Other Antithrombotic Agents

Aspirin does not prevent thromboembolic complications as effectively as warfarin does in patients with AF. In a meta-analysis of five

randomized clinical trials, aspirin reduced the risk for stroke by only 18%.⁷ In a recent large cohort study of patients with nonvalvular AF, aspirin had no therapeutic efficacy in preventing strokes.¹⁶ Therefore, if aspirin is used for prophylactic therapy, it should be used only in patients at lowest risk for thromboembolic complications (CHA₂DS₂-VASc score of 0). The 2011 American College of Cardiology/American Heart Association/Heart Rhythm Society guidelines still recommend aspirin for stroke prevention in patients with a CHADS₂ score of 0 and either aspirin or an oral anticoagulant when the CHADS₂ score is 1.¹⁸ Because of the negligible therapeutic effect of aspirin, a risk for bleeding complications that is close to the risk associated with oral anticoagulants, and the ability of the CHA₂DS₂-VASc score to accurately identify low-risk patients, the most recent guidelines of the European Society of Cardiology recommend no antithrombotic therapy when the CHA₂DS₂-VASc score is 0 and an individualized decision regarding no antithrombotic therapy versus an oral anticoagulant when the CHA₂DS₂-VASc score is 1.¹⁹

If aspirin is used for stroke prevention in patients with AF, the appropriate daily dose is 81 to 325 mg/day. No data are available to indicate superiority of a particular dose for prevention of thromboembolism.

In patients with a CHADS₂ score higher than 1 who are not able to tolerate anticoagulation with warfarin, combination therapy with aspirin and the platelet inhibitor clopidogrel is more efficacious than aspirin alone for prevention of thromboembolic complications. In a randomized, double-blind clinical trial (ACTIVE-A), all patients with AF and one or more risk factors for stroke who were not suitable candidates for anticoagulation with warfarin were treated with 75 to 100 mg/day of aspirin.²⁰ The patients were randomly assigned to also receive either 75 mg/day of clopidogrel or a matching placebo. The primary outcome was a composite of stroke, myocardial infarction, systemic embolism, and vascular death. When compared with placebo, clopidogrel reduced the risk for stroke by 28% and risk for the primary outcome by 11% but increased the risk for major hemorrhage. The study demonstrated that for every 1000 patients treated with the combination of aspirin plus clopidogrel instead of aspirin alone, 28 strokes (17 fatal or disabling) and 6 myocardial infarctions would be prevented, at a cost of 20 major bleeding episodes (3 fatal). Therefore, in high-risk patients who are not suitable candidates for warfarin, the benefits of combination therapy with aspirin plus clopidogrel outweigh the risk.

Warfarin

A meta-analysis of the major randomized clinical trials in which warfarin was compared with placebo for prevention of thromboembolism in patients with AF demonstrated that warfarin reduced the risk for all strokes (ischemic and hemorrhagic) by 61%.⁷ The target INR should be 2.0 to 3.0. This range of INRs provides the best balance between stroke prevention and hemorrhagic complications. In clinical practice, maintenance of the INR in the therapeutic range has been challenging, and a large proportion of patients often have an INR lower than 2.0. A large prospective study of community-based practices demonstrated that the mean time in the therapeutic range in patients treated with warfarin was just 66% and that the time in the therapeutic range was less than 60% in 34% of patients.²¹ Maintaining the INR at a level of 2.0 or higher is important because even a relatively small decrease in the INR from 2.0 to 1.7 more than doubles the risk for stroke. Furthermore, the data available indicate that the combination of aspirin and low-intensity anticoagulation with warfarin is inferior to warfarin in the standard therapeutic range for stroke prevention.

The annual risk for a major hemorrhagic complication during anticoagulation with warfarin is in the range of 1% to 2%, and a strong predictor of major bleeding events is an INR higher than 3.0. For example, the risk for intracranial bleeding is approximately twice as high at an INR of 4.0 than at 3.0. This emphasizes the importance of maintaining the INR in the range of 2.0 to 3.0.

Some studies have indicated that advanced age can be a risk factor for intracranial hemorrhage in patients with AF who are treated

with warfarin. The fear of hemorrhagic complications may lead some clinicians to favor the use of aspirin over warfarin in older adults. However, recent data indicate that the risk-to-benefit ratio of warfarin is more favorable than that of aspirin, even in patients older than 75 years. A randomized clinical trial (the Birmingham Atrial Fibrillation Treatment of the Aged Study) enrolled 973 patients older than 75 years (mean age, 82 years) with AF and randomly assigned them to treatment with 75 mg/day of aspirin or with warfarin adjusted to maintain an INR of 2.0 to 3.0.²² The primary endpoint was the composite of stroke (ischemic or hemorrhagic), intracranial hemorrhage, and arterial embolism, and the mean duration of follow-up was 2.7 years. The annual risk for the composite endpoint was significantly higher in the aspirin group (3.8%) than in the warfarin group (1.8%), even when the analysis was limited to patients older than 85 years. These data suggest that age should not be considered a contraindication to treatment with warfarin in patients with AF.

It is well established that genetic factors influence the dose of warfarin required to maintain the INR within the therapeutic range. Several single nucleotide polymorphisms that affect warfarin metabolism have been identified. Algorithms based on pharmacogenetic (see Chapter 9) and clinical factors improve the accuracy of warfarin dose initiation more than do algorithms based only on clinical factors, particularly for outliers who require 21 mg/wk or less or 49 mg/wk or more of warfarin to maintain a therapeutic INR.²³ However, a randomized study demonstrated that warfarin dosing that took into account the results of genotyping for *CYP2C9* (a cytochrome P-450 isoform) and *VKORC1* (a vitamin K epoxide reductase complex subunit) did not improve the time in the therapeutic range, which was approximately 70% in both groups.²⁴ Additional studies are required to determine whether the clinical benefits of genotyping of warfarin candidates justify the cost of genetic testing.

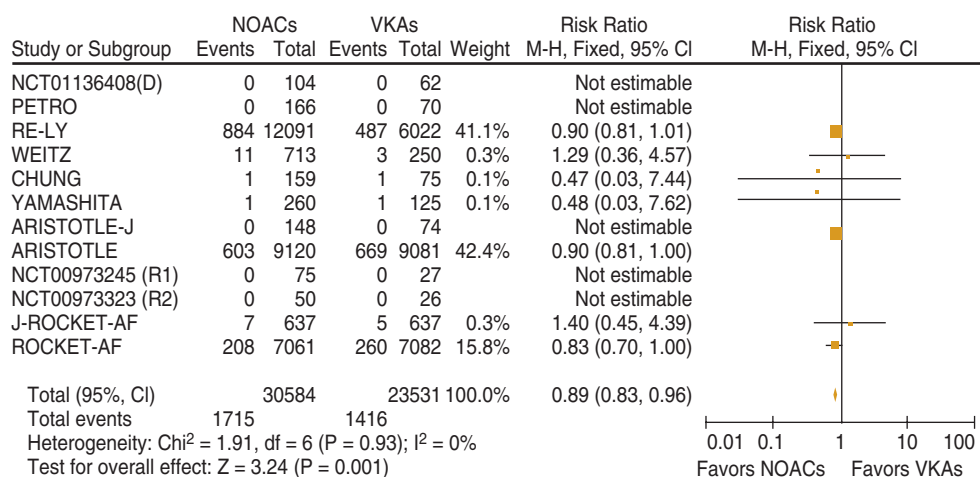

Newer Oral Anticoagulants

Direct thrombin inhibitors and factor Xa inhibitors have several advantages over vitamin K antagonists such as warfarin, the most notable being a fixed dosing regimen, which eliminates the need for monitoring of a laboratory test such as the INR. Dabigatran, an oral direct thrombin inhibitor, and rivaroxaban, a factor Xa inhibitor, were approved by the Food and Drug Administration for prevention of stroke/embolism in patients with nonvalvular AF in 2010 and 2011, respectively. Another factor Xa inhibitor, apixaban, was expected to gain Food and Drug Administration approval in 2013.

Randomized clinical trials have demonstrated that each of these three new oral anticoagulants is noninferior or superior to warfarin in efficacy and safety. These studies included patients with nonvalvular AF who had risk factors for stroke. In the RE-LY study, dabigatran at a dose of 150 mg twice daily was associated with a lower risk for stroke and systemic embolism than warfarin was and a similar rate of major hemorrhage.²⁵ In the ROCKET-AF study, rivaroxaban at a dose of 20 mg once daily was noninferior to warfarin for prevention of stroke/systemic embolism and was associated with a risk for major bleeding that did not differ from that of warfarin.²⁶ However, intracranial hemorrhage and fatal bleeding were less common with rivaroxaban. In the ARISTOTLE study, apixaban at a dose of 5 mg twice daily was superior to warfarin in prevention of stroke/systemic embolism and was associated with a lower risk for hemorrhagic complications and lower mortality (Fig. 38-7).²⁷

The newer oral anticoagulants, in addition to eliminating the need for laboratory monitoring, have other advantages over warfarin: fewer drug interactions, no food interactions, and a rapid onset of action that obviates the need for bridging therapy. However, they also have some disadvantages in comparison to warfarin: higher cost, more gastrointestinal side effects in the case of dabigatran, twice-daily dosing in the case of dabigatran and apixaban, and absence of a laboratory test to verify compliance. Furthermore, these agents cannot be used safely in patients with severe renal disease. Another limitation is that the effects of the newer anticoagulants may be difficult to reverse in patients with an overdose or hemorrhage. For example, in a 2011 study, a single bolus of 50 IU/kg of prothrombin

Total mortality

Cardiovascular mortality

complex concentrate was demonstrated to quickly and completely reverse the anticoagulant effect of rivaroxaban, but not dabigatran.²⁸ Nonetheless, for many patients with AF, the advantages of the newer anticoagulants outweigh the disadvantages.

The major professional societies have incorporated recommendations regarding the use of factor Xa and/or direct thrombin inhibitors into their most recent updates of guidelines for the management of AF. The practice guidelines of the American College of Cardiology/American Heart Association/Heart Rhythm Society recommend dabigatran as a useful alternative to warfarin for prevention of stroke/systemic embolism in patients with nonvalvular paroxysmal or persistent AF and risk factors for stroke. However, this recommendation is limited to patients without a prosthetic valve, with creatinine clearance lower than 15 mL/min, or with impaired clotting function as a result of advanced liver disease.²⁹ The European Society of Cardiology guidelines recommend dabigatran, rivaroxaban, or apixaban for patients with AF in whom maintenance of a therapeutic INR during treatment with warfarin is difficult and state that one of these newer anticoagulants should be considered instead of dose-adjusted warfarin for most patients with nonvalvular AF, based on their net clinical benefits.¹⁹ The guidelines also recommend that these agents not be

used in patients with a creatinine clearance lower than 30 mL/min.

An issue that has not been addressed in a randomized clinical trial is whether the newer oral anticoagulants provide adequate protection from the thromboembolic complications of transthoracic cardioversion. Although not studied prospectively, the safety of dabigatran in patients undergoing cardioversion was evaluated in a post hoc analysis of the RE-LY study.³⁰ A subset of 1336 patients underwent cardioversion after 3 weeks or more of treatment with dabigatran, 150 mg twice daily, or dose-adjusted warfarin with an INR of 2.0 to 3.0. The stroke/systemic embolism rate at 30 days did not differ significantly between the dabigatran group (0.3%) and the warfarin group (0.6%). There was also no difference between the two groups in the rate of major bleeding (0.6% in both groups). These data suggest that dabigatran is a safe and effective alternative to warfarin in patients requiring cardioversion. However, because patient compliance and a therapeutic effect of dabigatran cannot be confirmed by laboratory testing, a precardioversion transesophageal echocardiogram to rule out a left atrial thrombus may be appropriate more often in patients treated with dabigatran than in those treated with warfarin.

The onset of action of dabigatran, rivaroxaban, and apixaban is approximately 1.5 to 2 hours after a dose. The half-lives of dabigatran and apixaban range between 10 and 16 hours, and the half-life of rivaroxaban is 5 to

9 hours. These anticoagulants lose most of their effect by 24 hours after discontinuation. The rapid onset of action and washout eliminate the need for bridging therapy with heparin when treatment with one of the new anticoagulants is interrupted for a surgical or invasive procedure. In a recent study of patients treated with dabigatran who underwent radiofrequency catheter ablation of AF, dabigatran was withheld on the morning of the procedure.³¹ The study included a comparison group of patients who underwent radiofrequency catheter ablation of AF during uninterrupted therapy with warfarin at an INR of 2.0 to 3.0. Major hemorrhagic complications occurred significantly more often in the dabigatran group (6%) than in the warfarin group (1%). The results of this study demonstrate that dabigatran should be withheld for at least 24 hours before an invasive or surgical procedure.

Low-Molecular-Weight Heparin

Low-molecular-weight heparin has a longer half-life than unfractionated heparin does and a predictable antithrombotic effect that is attained with a fixed dosage administered subcutaneously twice a day. Because low-molecular-weight heparin can be self-injected by

patients outside the hospital, it is a practical alternative to unfractionated heparin for initiation of anticoagulation with warfarin in patients with AF. Bridging therapy with low-molecular heparin should be continued until the INR is 2.0 or higher.

Because of its high cost, low-molecular-weight heparin is rarely used in clinical practice as a substitute for long-term conventional anticoagulation. Low-molecular-weight heparin is typically used as a temporary bridge to therapeutic anticoagulation when therapy with warfarin is initiated or in high-risk patients for a few days before and after a medical or dental procedure when anticoagulation with warfarin has been suspended.

Excision or Closure of the Left Atrial Appendage

Approximately 90% of left atrial thrombi form in the appendage, and therefore successful excision or closure of the left atrial appendage should markedly reduce the risk for thromboembolic complications in patients with AF. Surgical techniques consist of either excision or closure by suturing or stapling. The efficacy of these techniques is variable and probably dependent on both technique and the operator. Postoperative transesophageal echocardiography demonstrated that the appendage was closed successfully in only 40% of 137 patients.³² The rate of successful closure was higher when the appendage was excised (73%) than when it was closed by suturing (23%). Of note is that complete closure was never achieved by stapling of the appendage. Left atrial appendage thrombi were never seen on transesophageal echocardiography after excision of the appendage but were observed in 41% of patients who underwent closure of the appendage. Therefore, transesophageal echocardiography should be performed after surgical closure of the left atrial appendage to confirm successful closure before discontinuation of anticoagulation.

Closure of the left atrial appendage can also be achieved percutaneously with an implanted device intended to seal the appendage. A randomized clinical trial (PROTECT AF) compared the efficacy of a percutaneous closure device versus warfarin for prevention of thromboembolic complications in 707 patients with AF and a CHADS₂ score of 1 or higher.³³ The device was found to be noninferior to warfarin for the primary efficacy composite endpoint of stroke, systemic emboli, and cardiovascular death and superior to warfarin for hemorrhagic stroke (91% reduction). The complication rate was approximately four times higher in the device arm, with the most common complication being pericardial effusion. The study demonstrated that percutaneous closure of the left atrial appendage is an effective alternative to warfarin in patients with AF. Another recent study showed that the risk for pericardial effusion declines significantly as operator experience increases.³⁴ Approval of the left atrial appendage closure device by the Food and Drug Administration awaits additional safety data.

It is likely that the left atrial appendage closure device will have its greatest utility in high-risk patients with AF who cannot tolerate or refuse to take an oral anticoagulant.

ACUTE MANAGEMENT OF ATRIAL FIBRILLATION

Patients who go to the emergency department because of AF generally have a rapid ventricular rate, and control of the ventricular rate is most rapidly achieved with intravenous diltiazem or esmolol. If the patient is hemodynamically unstable, immediate transthoracic cardioversion may be appropriate. If the AF has been present for more than 48 hours or if the duration is unclear and the patient is not already receiving an anticoagulant, cardioversion should be preceded by transesophageal echocardiography to rule out a left atrial thrombus.

If the patient is hemodynamically stable, the decision to restore sinus rhythm by cardioversion is based on several factors, including

symptoms, previous AF episodes, age, left atrial size, and current antiarrhythmic drug therapy. For example, in an elderly patient whose symptoms resolve once the ventricular rate is controlled and who has already had early recurrences of AF despite rhythm-control drug therapy, further attempts at cardioversion are not usually appropriate. On the other hand, cardioversion is generally appropriate for patients with symptomatic AF who are seen with a first episode of AF or who have had long intervals of sinus rhythm between previous episodes.

If cardioversion is decided on for a hemodynamically stable patient with AF that does not appear to be self-limited, two management decisions must be made: early versus delayed cardioversion and pharmacologic versus electrical cardioversion.

The advantages of early cardioversion are rapid relief of symptoms, avoidance of the need for transesophageal echocardiography or therapeutic anticoagulation for 3 to 4 weeks before cardioversion if it is performed within 48 hours of the onset of AF, and possibly a lower risk for early recurrence of AF because of less atrial remodeling (see Chapter 33). A reason to defer cardioversion is the unavailability of transesophageal echocardiography in an unanticoagulated patient with AF of unclear duration or a duration longer than 48 hours. Other reasons include a left atrial thrombus noted on transesophageal echocardiography (see Fig. 15-91), a suspicion (based on previous AF episodes) that AF will convert spontaneously within a few days, or a correctable cause of AF (e.g., hyperthyroidism).

When cardioversion is performed early in the course of an episode of AF, either pharmacologic or electrical cardioversion is an option. Pharmacologic cardioversion has the advantage of not requiring general anesthesia or deep sedation. In addition, the probability of an immediate recurrence of AF may be lower with pharmacologic cardioversion than with electrical cardioversion. However, pharmacologic cardioversion is associated with a risk for adverse drug effects and is not as effective as electrical cardioversion. Pharmacologic cardioversion is very unlikely to be effective if the duration of AF is longer than 7 days.

Drugs that can be administered intravenously for cardioversion of AF consist of ibutilide, procainamide, and amiodarone. For AF episodes shorter than 2 to 3 days in duration, the efficacy of these drugs is approximately 60% to 70% for ibutilide, 40% to 50% for amiodarone, and 30% to 40% for procainamide. To minimize the risk for QT prolongation and polymorphic ventricular tachycardia (torsades de pointes; see Chapter 37), use of ibutilide should be limited to patients with an ejection fraction higher than 35%. Acute pharmacologic cardioversion of AF can also be attempted with orally administered drugs in patients without structural heart disease. The most commonly used oral agents for acute conversion of AF are propafenone (300 to 600 mg) and flecainide (100 to 200 mg). It is prudent to administer these drugs under surveillance the first time that they are used. If no adverse drug effects are observed, the patient may then be an appropriate candidate for episodic, self-administered antiarrhythmic drug therapy on an outpatient basis.

The efficacy of transthoracic cardioversion is approximately 95%. Biphasic waveform shocks convert AF more effectively than do monophasic waveform shocks and allow the use of lower energy shocks, which result in a lower risk for skin irritation. An appropriate first-shock strength using a biphasic waveform is 150 to 200 J followed by higher output shocks if needed. If a 360-J biphasic shock is unsuccessful, ibutilide should be infused before another shock is delivered because it lowers the defibrillation energy requirement and improves the success rate of transthoracic cardioversion.

Two types of failure of transthoracic cardioversion occur in patients with AF. The first type is complete failure to restore sinus rhythm. In this situation, an increase in shock strength or infusion of ibutilide often results in successful cardioversion. The second type of failure is immediate recurrence of AF within a few seconds of successful conversion to sinus rhythm. The incidence of immediate recurrence of AF is approximately 25% for episodes shorter than 24 hours in duration and approximately 10% for episodes longer than 24 hours in duration. For this type of failure of cardioversion, an increase in shock strength is of no value. If the patient has not been receiving an

oral rhythm-control agent, infusion of ibutilide may be helpful for prevention of an immediate recurrence of AF.

Regardless of whether cardioversion is performed pharmacologically or electrically, therapeutic anticoagulation is necessary for 3 weeks or longer before cardioversion to prevent thromboembolic complications if the AF has been ongoing for more than 48 hours. If the time of onset of AF is unclear, for the sake of safety, the duration of AF should be assumed to be greater than 48 hours. These patients should receive therapeutic anticoagulation for 4 weeks after cardioversion to prevent the thromboembolic complications that may occur because of atrial stunning. If the duration of AF is known to be less than 48 hours, cardioversion can be performed without anticoagulation. To improve the safety margin, it may be appropriate to use a 24-hour cutoff for the AF duration, which allows safe cardioversion without anticoagulation.

When the duration of AF is longer than 48 hours or unclear, an alternative to 3 weeks of therapeutic anticoagulation before cardioversion is anticoagulation with heparin and transesophageal echocardiography to check for a left atrial thrombus. If no thrombi are seen, the patient can safely be cardioverted but still requires 4 weeks of therapeutic anticoagulation after cardioversion to prevent thromboembolism related to atrial stunning. The major clinical benefit of the transesophageal echocardiography-guided approach over the conventional approach is that sinus rhythm is restored several weeks sooner. When compared with the conventional approach, the transesophageal echocardiography-guided approach has not been found to reduce the risk for stroke or major bleeding or to affect the proportion of patients still in sinus rhythm at 8 weeks after cardioversion.

LONG-TERM MANAGEMENT OF ATRIAL FIBRILLATION

Pharmacologic Rate Control Versus Rhythm Control

Several randomized studies have compared a rate-control strategy with a rhythm-control strategy in patients with AF. The largest study by far was the AFFIRM study, which consisted of 4060 patients with a mean age of 70 years who had AF for 6 hours to 6 months.³⁵ At 5 years of follow-up, the prevalence of sinus rhythm was 35% in the rate-control arm and 63% in the rhythm-control arm. No significant difference was noted between the two study arms in total mortality, stroke rate, or quality of life. The percentage of patients requiring hospitalization was significantly lower in the rate-control arm (73%) than in the rhythm-control arm (80%), and the incidence of adverse drug effects such as torsades de pointes was also significantly lower in the rate-control arm (0.2% versus 0.8%). The authors of the AFFIRM study concluded that there is no survival advantage of a rhythm-control strategy over a rate-control strategy and that a rate-control strategy has advantages such as a lower probability of hospitalization and adverse drug effects.

In a post hoc analysis of the AFFIRM study, the relationship between sinus rhythm, treatment, and survival was determined by an on-treatment analysis instead of the intention-to-treat analysis used in the original report.³⁶ Sinus rhythm was found to be independently associated with lower mortality (hazard ratio, 0.53), and antiarrhythmic drug therapy was independently associated with increased mortality (hazard ratio, 1.49). Therefore, the potential benefit of maintaining sinus rhythm with antiarrhythmic drugs was negated by the adverse effects of the antiarrhythmic drug therapy. This suggested that therapies that maintain sinus rhythm without major adverse effects may have a beneficial effect on survival.

The results of the AFFIRM study should not be applied routinely to all patients with AF. The decision to pursue a rhythm-control strategy versus a rate-control strategy should be individualized, with several factors being taken into account, including the nature, frequency, and severity of symptoms; the length of time that AF has been present continuously in patients with persistent AF; left atrial size; comorbid conditions; the response to previous cardioversions; age; the side

effects and efficacy of the antiarrhythmic drugs already used to treat the patient; and the patient's preference.

The AFFIRM study convincingly demonstrated that a rate-control strategy is preferable to a rhythm-control strategy in asymptomatic or minimally symptomatic patients 65 years or older. In patients with persistent AF, it is reasonable to attempt to restore sinus rhythm with antiarrhythmic drug therapy or transthoracic cardioversion at least once in individuals 65 years or younger and in those 65 years or older whose AF is symptomatic despite adequate heart rate control. If the AF has been continuous for longer than 1 year or if the left atrial diameter is very large (>5.0 cm), there is a high probability of an early recurrence of AF, and this should be taken into account in deciding on the best strategy. After cardioversion, the decision to maintain the patient on antiarrhythmic drug therapy to delay the next episode of AF is based on the patient's preference, the perceived risk for early recurrence of AF, and the duration of sinus rhythm between previous cardioversions. Treatment by cardioversion without daily antiarrhythmic drug therapy is acceptable if the episodes of AF are separated by at least 6 months. Treatment with a rhythm-control drug is usually appropriate when AF recurs within a few months of cardioversion.

The most realistic goal of antiarrhythmic drug therapy in patients with persistent AF is to delay the onset of the next episode by at least several months, not for several years. It is often appropriate to continue therapy with a particular antiarrhythmic drug if recurrences of AF are limited to approximately one episode per year.

In patients with symptomatic paroxysmal AF, the aggressiveness with which a rhythm-control strategy is pursued should be dictated by the frequency and severity of symptoms and how well antiarrhythmic drug therapy is tolerated. Drug therapy is more likely to be judged successful when patients are reminded that the goal of therapy is not complete suppression of AF but a clinically meaningful reduction in the frequency, duration, and severity of episodes.

A pharmacologic rhythm-control strategy need not necessarily consist of daily drug therapy. Episodic drug therapy (the "pill-in-the-pocket" approach) is useful for patients whose episodes of AF are relatively infrequent. Episodic drug therapy is a reasonable option for patients who are clearly aware of the onset and termination of the AF episodes and who have lone AF or only minimal structural heart disease. A typical drug regimen consists of a class IC drug (flecainide or propafenone) plus a short-acting beta blocker (e.g., propranolol) or calcium channel blocker (e.g., verapamil) for rate control. Many patients with infrequent episodes prefer this approach because it eliminates the inconvenience, cost, and possible side effects of daily prophylactic therapy. However, patients who are disabled by severe symptoms during AF may prefer daily prophylactic therapy even if the episodes are infrequent.

Many patients with symptomatic AF also have asymptomatic episodes. Therefore, daily antithrombotic therapy to prevent thromboembolic events is appropriate for *all* patients being treated for recurrent AF, whether it is persistent or paroxysmal and whether a rhythm-control or rate-control strategy is used. The choice of no therapy, an oral anticoagulant, aspirin, or the combination of aspirin plus clopidogrel should be dictated by an analysis of risk factors and drug tolerance.

Pharmacologic Rate Control

An excessively rapid ventricular rate during AF often results in uncomfortable symptoms and decreased effort tolerance and can cause a tachycardia-induced cardiomyopathy if it is sustained for several weeks to months. Optimal heart rates during AF vary with age and should be similar to the heart rates that a patient would have at a particular degree of exertion during sinus rhythm. Heart rate control must be assessed both at rest and during exertion. At rest, the ideal ventricular rate during AF is in the range of 60 to 75 beats/min. During mild to moderate exertion (e.g., rapid walking), the target rate should be 90 to 115 beats/min; and during strenuous exercise, the ideal rate is in the range of 120 to 160 beats/min. Optimal assessment of the degree of heart rate control is provided by an ambulatory 24-hour Holter recording or an exercise test.

Oral agents available for long-term heart rate control in patients with AF are digitalis, beta blockers, calcium channel antagonists, and amiodarone. The first-line agents for rate control are beta blockers and the calcium channel antagonists verapamil and diltiazem. A combination is often used to improve efficacy or to limit side effects by allowing the use of smaller dosages of the individual drugs. In patients with sinus node dysfunction and tachy-brady syndrome, use of a beta blocker with intrinsic sympathomimetic activity (pindolol, acebutolol) may provide rate control without aggravating the sinus bradycardia.

Digitalis may adequately control the rate at rest but often does not provide adequate rate control during exertion. Its use is appropriate in patients with systolic heart failure, in whom digitalis has been shown to improve outcomes such as heart failure and all-cause hospitalization. In patients with the vagotonic form of paroxysmal AF, the vagotonic effect of digitalis may promote AF. Furthermore, in patients without systolic heart failure, use of a digitalis glycoside may have a deleterious effect on survival. In a large anticoagulation trial that compared warfarin with a direct thrombin inhibitor (SPORTIF III-IV), digitalis was found to be independently associated with a 53% higher risk for all-cause mortality.³⁷ Although this was demonstrated by post hoc analysis and not by a randomized comparison of digitalis versus placebo, the results are of enough concern to limit the use of digitalis to patients with heart failure.

Amiodarone is much less frequently used for rate control than the other negative dromotropic agents because of the risk for organ toxicity associated with long-term therapy. Amiodarone may be an appropriate choice for rate control if the other agents are not tolerated or are ineffective. As an example, amiodarone would be an appropriate choice for a patient with persistent AF, heart failure, and reactive airway disease who cannot tolerate either a calcium channel antagonist or a beta blocker and who has a rapid ventricular rate despite treatment with digitalis.

Strict heart rate control can be difficult to achieve pharmacologically. The effects of a lenient rate-control strategy (resting rate <110 beats/min) and a strict rate-control strategy (resting heart rate <80 beats/min, rate during moderate exercise <110 beats/min) on outcomes were compared in randomized fashion in 614 patients with persistent AF.³⁸ The primary composite outcome was cardiovascular death, heart failure hospitalizations, stroke, embolism, major bleeding episodes, and major arrhythmic events. The heart rate target was achieved in 98% of patients in the lenient rate-control group versus 67% in the strict rate-control group. The incidence of the primary outcome at 3 years did not differ significantly between the lenient rate-control group (12.9%) and the strict rate-control group (14.9%). The results suggest that strict rate control has no advantages over lenient rate control. However, the study did not present data on the severity of symptoms, exercise capacity, or left ventricular ejection fraction, and follow-up was limited to 3 years. Strict rate control is still often an appropriate goal for relief of symptoms, improvement in functional capacity, and avoidance of tachycardia-induced cardiomyopathy during long-term follow-up.

Pharmacologic Rhythm Control

The results of published studies on the efficacy of antiarrhythmic drugs for AF suggest that all the drugs available except amiodarone have similar efficacy and are associated with a 50% to 60% reduction in the odds of recurrent AF during 1 year of treatment. The one drug that stands out as having higher efficacy than the others is amiodarone. In studies that directly compared amiodarone with sotalol or class I drugs, amiodarone was 60% to 70% more effective in suppressing AF. However, because of its risk for organ toxicity, amiodarone is not appropriate first-line drug therapy for many patients with AF. Because the efficacy of rhythm-control agents other than amiodarone is in the same general range, selection of an antiarrhythmic drug to prevent AF is often dictated by the issues of safety and side effects.

Ventricular proarrhythmia from class IA agents (quinidine, procainamide, disopyramide) and class III agents (sotalol, dofetilide, dronedarone, amiodarone) is manifested as QT prolongation and

polymorphic ventricular tachycardia (torsades de pointes). Risk factors for this type of proarrhythmia include female sex, left ventricular dysfunction, and hypokalemia. The risk for torsades de pointes appears to be much lower with dronedarone and amiodarone than with the other class III drugs. The ventricular proarrhythmia resulting from class IC agents (flecainide and propafenone) is manifested as monomorphic ventricular tachycardia, sometimes associated with widening of the QRS complex during sinus rhythm, but not with QT prolongation. Published studies indicate that the drugs most likely to result in ventricular proarrhythmia are quinidine, flecainide, sotalol, and dofetilide. In controlled studies, these agents increased the risk for ventricular tachycardia by a factor of 2 to 6.

Adverse drug events resulting in discontinuation of drug therapy are fairly common with rhythm-control drugs. Withdrawal because of adverse effects is most frequent with quinidine, disopyramide, flecainide, sotalol, and amiodarone. A review of studies in which 32 treatment arms received an antiarrhythmic drug for AF found that 10.4% of patients discontinued drug therapy because of an adverse drug event, most commonly gastrointestinal side effects and neuropathy.³⁹

The best options for drug therapy to suppress AF depend on the patient's comorbid conditions. In patients with lone AF or minimal heart disease (e.g., mild left ventricular hypertrophy), flecainide, propafenone, sotalol, and dronedarone are reasonable first-line drugs, and amiodarone and dofetilide can be considered if the first-line agents are ineffective or not tolerated. In patients with substantial left ventricular hypertrophy (left ventricular wall thickness >13 mm), the hypertrophy heightens the risk for ventricular proarrhythmia, and the safest choice for drug therapy is amiodarone. In patients with coronary artery disease, several of the class I drugs have been found to increase the risk for death, and the safest first-line options are dofetilide, sotalol, and dronedarone, with amiodarone being reserved for use as a second-line agent. In patients with heart failure, several antiarrhythmic drugs have been associated with increased mortality, and the only two drugs known to have a neutral effect on survival are amiodarone and dofetilide (see Chapter 35).

At the time of its approval by the Food and Drug Administration, dronedarone was known to increase mortality in patients with class IV heart failure or those with a recent episode of decompensated heart failure. After approval, the categories of patients in whom dronedarone is contraindicated expanded. A randomized study (PALLAS) was terminated prematurely when it was found that dronedarone increased the risk for heart failure, stroke, and cardiovascular death in the following categories of patients: (1) 65 years or older with permanent AF and either coronary artery disease, previous stroke, or symptomatic heart failure and (2) 75 years or older with hypertension and diabetes.⁴⁰

Rhythm Control with Agents Other Than Antiarrhythmic Drugs

Experimental studies indicate that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) have favorable effects on electrical and structural remodeling (see Chapter 33). This explains why ACE inhibitors and ARBs have been shown in some studies to prevent AF. However, other studies have demonstrated that these agents do not prevent AF. For example, in a randomized clinical trial of the ARB valsartan versus placebo in 1442 patients with structural heart disease and recurrent AF, the AF recurrence rate was approximately 50% in both study arms, and there was no evidence that valsartan prevented AF.⁴¹ Therefore, at present the evidence is insufficient to support the use of ACE inhibitors and ARBs for the sole purpose of preventing AF.

Some evidence indicates that statins prevent AF, perhaps because of their anti-inflammatory effects. A systematic review of 10 observational studies demonstrated a 23% reduction in the relative risk for AF in patients treated with statins.⁴² However, a meta-analysis of six randomized clinical trials concluded that statins do not prevent AF, except after open heart surgery.⁴² Therefore, the data available do not support the use of statins for the prevention of AF.

Omega-3 polyunsaturated fatty acids (PUFAs) have an anti-inflammatory effect and can also have direct ion channel effects. Several studies in which treatment with omega-3 PUFAs was initiated at the time of cardioversion of AF demonstrated no prevention of recurrent AF. However, omega-3 PUFAs did prevent recurrent AF after cardioversion of persistent AF in two prospective randomized studies in which patients were pretreated with 2 to 6 g/day of fish oil for 1 month before cardioversion.^{43,44} Almost all patients in these studies also received amiodarone or sotalolol. The rationale for pretreatment with the fish oil was to allow enough time for the omega-3 PUFAs to become incorporated into cell membranes and exert their ion channel effects. These data suggest that fish oil can be helpful in preventing recurrent AF when used in combination with an antiarrhythmic drug after cardioversion of persistent AF.

NONPHARMACOLOGIC MANAGEMENT OF ATRIAL FIBRILLATION

Pacing to Prevent Atrial Fibrillation

Randomized clinical trials comparing dual-chamber (DDD) pacing with right ventricular pacing have concluded that atrial pacing prevents AF. Studies suggest that the higher incidence of AF during ventricular pacing than during DDD pacing may be at least partially due to a proarrhythmic effect of ventricular pacing, not only to a suppressive effect of atrial pacing.

Studies involving small numbers of patients have suggested that dual-site right atrial pacing or pacing of the interatrial septum near the Bachmann bundle prevents AF. Although it is possible that these atrial pacing techniques decrease the propensity for AF, the magnitude of the effect appears to be minimal.

Some antibradycardia pacemakers are designed to prevent and terminate AF. Pacing algorithms to prevent AF consist of atrial pacing to prevent suppression of postextrasystolic pauses and acceleration of the atrial pacing rate when repetitive premature atrial complexes are sensed. When these pacing algorithms have been evaluated in rigorous fashion, they have been found to be ineffective or at best minimally effective in reducing the AF burden. Antitachycardia pacing (ATP) to terminate AF consists of a burst of rapid atrial pacing at the onset of AF. ATP may be useful for termination of atrial flutter or atrial tachycardia, but it is rarely if ever effective for AF.

Because of insufficient evidence to support its use, atrial pacing is not indicated for prevention of AF in patients without bradycardia. In patients with a bradycardia indication for a pacemaker and paroxysmal AF or recurrent episodes of persistent AF, the data available clearly support the use of atrial-based pacing and programming to minimize the amount of ventricular pacing.

Catheter Ablation of Atrial Fibrillation

Challenges of Ablating Atrial Fibrillation

Catheter ablation reliably and permanently eliminates several types of arrhythmia, such as AV nodal reentrant tachycardia and accessory pathway-mediated tachycardias³⁶ (see Chapters 35 and 37). Success rates greater than 95% are attainable when the arrhythmia substrate is well defined, localized, and temporally stable. In contrast, the arrhythmia substrate of AF is not well understood, is usually widespread, is variable between patients, and may be progressive. Furthermore, several factors that promote AF cannot be addressed simply by catheter ablation, including comorbid conditions such as hypertension and obstructive sleep apnea, structural remodeling of the atria, inflammatory factors, and genetic factors (see Chapter 8). Therefore, even though late recurrences of AV nodal reentrant tachycardia or accessory pathway conduction are very rare, AF can recur more than 2 or 3 years after an initially successful ablation procedure.

Selection of Patients

Given the limitations of catheter ablation of AF, it is usually appropriate to treat patients with at least one rhythm-control drug before

catheter ablation is considered, particularly if the AF is persistent, because the efficacy of catheter ablation is lower for persistent AF than for paroxysmal AF. The most appropriate candidates for catheter ablation have symptomatic AF that is affecting their quality of life and has not responded adequately to drug therapy. The ideal candidate has lone AF or only minimal structural heart disease. The recommendation for catheter ablation should be influenced by the estimated probability of success, and the procedure is least likely to be successful if the left atrium is markedly dilated or if the AF has been persistent for more than 4 years.

Catheter ablation of AF is generally contraindicated in patients who have a left atrial thrombus or who cannot tolerate anticoagulation for at least 6 to 8 weeks after ablation. Catheter ablation is also usually inappropriate in asymptomatic individuals with a CHA₂DS₂-VASc score higher than 1 whose only motivation to undergo the procedure is to eliminate the need for anticoagulation.

In a recent study, patients with symptomatic paroxysmal AF and no previous rhythm-control therapy were randomly assigned to undergo catheter ablation or treatment with an antiarrhythmic drug.⁴⁵ This study demonstrated that the cumulative AF burden at 2 years of follow-up did not differ significantly between the two groups. This result validates the recommendation that catheter ablation be reserved for patients who have not responded adequately to treatment with an antiarrhythmic drug. However, catheter ablation can be appropriate first-line therapy in some patients with AF: those younger than 35 years with symptomatic AF, those with sinus node dysfunction in whom antiarrhythmic drug therapy is likely to create the need for a permanent pacemaker, and patients who express an aversion to drug therapy.

Radiofrequency Catheter Ablation

The most commonly used energy to eliminate paroxysmal AF by catheter ablation is radiofrequency energy delivered through an irrigated-tip catheter. Radiofrequency energy is delivered point by point, typically in association with a three-dimensional electroanatomic mapping system as a navigation guide and to create a visual record of the sites that have already been ablated. To improve anatomic accuracy, the electroanatomic map of the left atrium can be merged with a computed tomography scan or magnetic resonance image of the left atrium and pulmonary veins (Fig. 38-8) or with an ultrasound image generated by intracardiac echocardiography.

Because of their important role in triggering and maintaining episodes of AF, almost all ablation strategies include electrical isolation

FIGURE 38-8 Electroanatomic map of the left atrium merged with a computed tomography scan of the left atrium and pulmonary veins. The red and gray tags indicate the sites at which radiofrequency energy was delivered in the antrum of the pulmonary veins. LI = left inferior pulmonary vein; LS = left superior pulmonary vein; RS = right superior pulmonary vein.

FIGURE 38-9 Tachycardia with a cycle length of 80 msec arising in a left inferior pulmonary vein. This tachycardia was responsible for generating AF. During radiofrequency ablation in the antrum of this pulmonary vein, AF terminated (arrow) and converted to sinus rhythm when the pulmonary vein became electrically isolated. The sinus beats are indicated with asterisks. The pulmonary vein tachycardia was still present inside the vein. Shown are leads I and V₁, the electrograms recorded by the ablation catheter (Abl) outside the left inferior pulmonary vein (LIPV) and by a ring catheter in the LIPV, and the coronary sinus electrograms (CS).

of the pulmonary veins (Fig. 38-9 and Video 38-1). Such isolation can be accomplished by either ostial ablation or wide-area ablation 1 to 2 cm away from the ostia, in the antral regions of the pulmonary veins. Most of the data available indicate that wide-area ablation is more effective than ostial ablation, probably because it also targets drivers that are in the antrum, outside the pulmonary vein itself.⁴⁶ Triggers of AF can also arise from other thoracic veins, such as the superior vena cava, coronary sinus, and the vein of Marshall. After the pulmonary veins have been isolated, infusion of isoproterenol is helpful to determine whether any non-pulmonary vein triggers are present.

Pulmonary vein isolation is often sufficient to eliminate paroxysmal AF but is usually insufficient for persistent AF. A variety of ablation strategies have been used for persistent AF after the pulmonary veins have been isolated: linear ablation across the left atrial roof, mitral isthmus, or cavotricuspid isthmus; ablation of CFAEs in the left atrium, coronary sinus, or right atrium; various combinations of linear and CFAE ablation; and ablation of ganglionated plexuses.⁴⁶ The endpoint of catheter ablation of persistent AF is either completion of a prespecified lesion set (in which case sinus rhythm is restored by cardioversion) or stepwise ablation until the AF converts to sinus rhythm.

A novel approach to ablation of AF is based on the hypothesis that AF is sustained by localized sources, either rotors and/or focal impulses.⁵ Signal processing with proprietary software allowed identification of focal impulses and rotors, which were then targeted for radiofrequency ablation during ongoing episodes of AF. A mean of 2.1 localized sources per patient were identified in 97% of 101 patients. Termination or slowing of AF was successfully achieved by ablation

of the localized sources in 86% of cases. At a median of 9 months of follow-up, 82% of patients were free of AF versus 45% of those in a control group who underwent conventional ablation. These early results suggest that focal impulse and rotor modulation can improve outcomes of catheter ablation of AF.

Based on an extensive review of a large number of published reports, the overall single-procedure success rate of radiofrequency catheter ablation of AF without antiarrhythmic drug therapy is 57%, and the multiple-procedure success rate is 71%.³⁹ Efficacy is strongly influenced by the type of AF being ablated. For paroxysmal AF, a single-procedure success rate of 60% to 75% is expected at experienced centers, whereas for persistent AF, the single-procedure success rate is typically 50% or lower.

The efficacy of radiofrequency catheter ablation of AF compares favorably with that of antiarrhythmic drug therapy. In a meta-analysis of four prospective, randomized studies, radiofrequency catheter ablation was found to result in AF-free survival significantly more often than antiarrhythmic drug therapy was (76% versus 19%).⁴⁷ In a multicenter study of 112 patients with paroxysmal AF resistant to one or more antiarrhythmic drugs, the patients were randomly assigned to pulmonary vein isolation plus additional ablation at the operator's discretion or antiarrhythmic drug therapy.⁴⁸ The AF-free survival rate at 12 months was 89% in the ablation arm after a median of two procedures per patient versus 23% in the drug arm.

When the efficacy of catheter ablation of AF is evaluated, recurrences of AF in the first 3 months after ablation are usually ignored. A 3-month blanking period excludes early recurrences that are

**VIDEO 38-1**

Pulmonary vein (PV) isolation using image integration. A semi-transparent computed tomography “cast” of the left atrium appears in orange, viewed first from an anterior perspective. As the movie runs, black dots appear at sites sampled by a roving mapping catheter in order to form a “shell” of the inner contours of the left atrium. The image rotates to be viewed from the right side and then from the left. Once this acquisition is completed, larger red circles appear at sites at which radiofrequency energy is delivered to electrically isolate the PVs by encircling their orifices with ablation lesions, starting with the left PVs and ending with the right PVs. The image is rotated to allow viewing of the process from different angles.

caused by a transient inflammatory response or incomplete lesion maturation.

Even in patients with symptomatic AF, postablation recurrences can be asymptomatic. Therefore, accurate assessment of efficacy requires monitoring for at least 7 days and preferably for 1 month with a device capable of detecting asymptomatic episodes of AF. Ideally, the monitoring should be performed at 6 and 12 months after the procedure.

Most recurrences of AF after radiofrequency catheter ablation occur within the first year of follow-up. However, recurrences continue to occur at a rate of approximately 5% to 6% per year for several years after ablation.⁴⁹ Ongoing comorbid conditions such as valvular heart disease, obstructive sleep apnea, and hypertension can contribute to late recurrences of AF. Another probable cause of late recurrences of AF in patients who have undergone pulmonary vein isolation is delayed recovery from radiofrequency-induced injury leading to reconnection of the pulmonary veins.⁵⁰

Atrial tachyarrhythmias that occur after catheter ablation of AF can take the form of atrial tachycardia/flutter, which can be either focal or reentrant. When the ablation strategy consists of only pulmonary vein isolation, postablation focal atrial tachycardias are often attributable to partial recovery of pulmonary vein conduction. The incidence of reentrant atrial tachycardia/flutter after ablation is related to the extent of ablation at atrial sites other than the pulmonary vein. When extensive ablation is performed in the left atrium or in both atria in an attempt to convert AF to sinus rhythm, atrial tachycardia/flutter occurs during follow-up in more than 50% of patients. These arrhythmias do not respond well to antiarrhythmic drug therapy and frequently require another ablation procedure for elimination.

The risk for a major complication after radiofrequency catheter ablation of AF is reported to be 5% to 6%.^{39,51} In a large international survey, the most common major complications were cardiac tamponade (1.2%), pulmonary vein stenosis (1.3%), and cerebral thromboembolism (0.94%).⁵¹ The risk for vascular injury is reported to be 1% to 2%. The risk for an atrioesophageal fistula is probably less than 0.1%. Despite its rarity, this complication is of great concern because it is often lethal.

Large international surveys have reported the risk for a fatal complication to be in the range of 0.05% to 0.1%.^{51,52} In a survey of 32,569 patients who underwent catheter ablation of AF, the mortality rate was 0.1%, and the most common causes of death were cardiac tamponade (25% of deaths), stroke (16%), atrioesophageal fistula (16%), and pneumonia (16%).⁵²

A recently recognized complication of radiofrequency ablation is silent cerebral ischemic lesions. Cerebral magnetic resonance imaging demonstrated silent cerebral ischemic lesions in 14% of patients in whom an irrigated-tip radiofrequency ablation catheter was used.⁵³ The long-term clinical significance of these lesions is unclear.

Cryoballoon Ablation

In 2010, a cryoballoon catheter designed to isolate the pulmonary veins became widely available for use in the United States. In contrast to point-by-point radiofrequency ablation around pulmonary veins, the cryoballoon is designed to fit into the antrum of a pulmonary vein and to create a circumferential ablative lesion via cryoenergy (Fig. 38-10). An advantage of cryoenergy over radiofrequency energy is that it is much less likely to cause pulmonary vein stenosis or esophageal injury. Experienced operators can achieve complete pulmonary vein isolation acutely by using only the cryoballoon catheter in 98% of patients.⁵⁴ In patients with paroxysmal AF, 1-year freedom from AF is achieved in approximately 75% of patients.⁵⁴ Randomized studies have demonstrated no significant difference in freedom from AF at 1 year between cryoballoon ablation and radiofrequency ablation.⁵⁴

The most frequent complication of cryoballoon ablation is phrenic nerve palsy, which has an incidence of approximately 7%.⁵⁴ The phrenic nerve palsy resolves within 1 year in almost all patients. In one study, endoscopy showed esophageal ulcerations in 17% of 35 patients after cryoballoon ablation, but two other studies reported that there was no evidence of thermal esophageal injury in 81 patients

FIGURE 38-10 Cryoballoon catheter positioned in the antrum of the right superior pulmonary vein. The balloon is inflated and there is no leakage of contrast material injected through the lumen of the cryoballoon catheter into the vein. A diagnostic ring catheter is positioned within the vein. Pulmonary vein isolation was achieved with two 4-minute applications of cryoenergy through the balloon.

who underwent endoscopy after cryoballoon ablation. Pulmonary vein stenosis causing symptoms or requiring intervention is very infrequent (0.2%), as are thromboembolic complications (0.6%). Cardiac tamponade has occurred in 0.6% of patients and vascular access complications in approximately 2%.

Remote Magnetic Navigation

Two systems are currently available for remote navigation of a radiofrequency ablation catheter. In one system, large magnets are positioned on each side of the patient, and small magnets embedded in the tip of the ablation catheter allow remote navigation by shifting the magnetic field vectors. With the other system, an ablation catheter is navigated remotely by a robotic steerable sheath system. The advantages of these systems are improved catheter stability, marked reduction in exposure of the operator to radiation, and avoidance of the technical challenges of manual catheter manipulation. The experience to date with remote magnetic navigation indicates that the efficacy and safety of radiofrequency catheter ablation of AF are comparable to those of conventional radiofrequency catheter ablation.⁵⁵

Ablation of the Atrioventricular Node

Radiofrequency catheter ablation of the AV node results in complete AV nodal blockade and substitutes a regular, paced rhythm for an irregular and rapid native rhythm. It is a useful strategy in patients who are symptomatic from AF because of a rapid ventricular rate that cannot be adequately controlled pharmacologically as a result of either inefficacy or intolerance to rate-control drugs and who either are not good candidates for ablation of the AF or already have undergone an unsuccessful attempt at ablation of the AF.

In patients with AF and an uncontrolled ventricular rate, AV node ablation improves the left ventricular ejection fraction in those with tachycardia-induced cardiomyopathy. AV node ablation has also been shown to improve symptoms, quality of life, and functional capacity and to reduce the use of health care resources. There is no

evidence that AV node ablation is of benefit in patients whose ventricular rate is well controlled by medications.

Disadvantages of AV node ablation are that it creates a life-long need for ventricular pacing and does not restore AV synchrony. Although symptoms and functional capacity typically improve after AV node ablation in patients with AF and an uncontrolled ventricular rate, some patients may not feel as well as during sinus rhythm.

AV node ablation is a technically simple procedure with an acute and long-term success rate of 98% or higher and a very low risk for complications. In patients with persistent AF, a ventricular pacemaker is implanted. A dual-chamber pacemaker is appropriate if the AF is paroxysmal. Most patients have a good clinical outcome with right ventricular pacing, but in those with borderline or depressed left ventricular function, biventricular pacing for cardiac resynchronization therapy is appropriate. In patients with ischemic or nonischemic cardiomyopathy and an ejection fraction from 30% or lower to 35%, an ICD may be appropriate for primary prevention of sudden death. However, a simple pacemaker without the ICD is often adequate for patients with a borderline ejection fraction (30% to 35%) and a rapid ventricular rate because the ejection fraction is likely to improve to greater than 35% after the ventricular rate has been controlled by AV node ablation.

Surgical Approaches to Atrial Fibrillation

The most effective surgical procedure for AF is the “cut-and-sew” maze procedure developed by Cox in 1987.⁵⁶ This operation involves 12 atrial incisions to isolate the pulmonary veins and create lines of block in the left atrium and right atrium. In addition, the left and right atrial appendages are excised. Rates of long-term freedom from AF after the Cox maze procedure are reported to range from 70% to 95%, but 10% to 35% of patients still require antiarrhythmic drug therapy. The efficacy of the Cox maze procedure is lower in patients with a very large left atrium or with persistent AF for many years. The Cox maze procedure has not been widely performed because it requires cardiopulmonary bypass, is technically difficult, and is associated with a mortality rate of approximately 1% to 2%.

A large variety of surgical ablation tools have been developed to simplify the classic Cox maze procedure. These tools allow the surgeon to substitute an ablation line for a surgical incision. Several different types of energy have been used for surgical ablation: radiofrequency energy, cryoenergy, microwave, laser, and high-intensity focused ultrasound. The tool that most consistently produces transmural ablation lines is a clamp device intended to isolate the pulmonary veins with bipolar radiofrequency energy.

Various surgical ablation strategies have been used, including pulmonary vein isolation, left atrial ablation, and the Cox maze lesion set. The left atrial appendage is usually excluded and ganglionic plexuses are often also ablated. In patients who do not require concomitant coronary artery bypass grafting or valve repair or replacement, surgical ablation is typically performed via a thorascopic, minimally invasive epicardial approach. Single-procedure success rates at 1 year of follow-up have ranged from 65% to 86%.^{57,58}

Radiofrequency catheter ablation of AF was compared with surgical ablation in a randomized study that selected patients with drug-refractory AF who had hypertension and left atrial dilation or who had already undergone unsuccessful catheter ablation.⁵⁹ Freedom from AF at 1 year was significantly higher in the surgical group (65.6%) than in the catheter ablation group (36.5%). However, substantial procedural adverse events also occurred significantly more often with surgical ablation (23%) than with catheter ablation (3.2%). The most common complications of surgical ablation were hemothorax and bradycardia requiring pacemaker implantation.

Surgical therapy for AF is appropriate as a concomitant procedure in patients undergoing open heart surgery for coronary artery disease or valvular disease. A stand-alone surgical procedure for AF is an option for patients who have not had a successful outcome from catheter ablation, who are not good candidates for catheter ablation, or who prefer a surgical procedure over catheter ablation.

SPECIFIC CLINICAL SYNDROMES

Postoperative Atrial Fibrillation

AF is common after open heart surgery and is reported to occur in 25% to 40% of patients who undergo coronary artery bypass graft surgery or valve replacement (see Chapter 80). It is associated with a twofold increase in the risk for postoperative stroke and is the most common reason for prolonged hospitalization. The risk for AF peaks on the second postoperative day. The pathogenesis of postoperative AF is multifactorial and probably involves adrenergic activation, inflammation, atrial ischemia, electrolyte disturbances, and genetic factors. Several risk factors for AF after open heart surgery have been identified, including age older than 70 years, history of previous AF, male sex, left ventricular dysfunction, left atrial enlargement, chronic lung disease, diabetes, and obesity.

The antiarrhythmic drugs that have been shown to decrease the risk for postoperative AF are beta blockers, sotalol, and amiodarone. Amiodarone and sotalol decrease the risk for postoperative AF by 50% to 65%, and beta blockers appear to be somewhat less effective, decreasing the risk by approximately 30%.

Hypomagnesemia is common after open heart surgery and can heighten the risk for AF. Magnesium administration immediately preoperatively, perioperatively, or postoperatively is reported to decrease the risk for postoperative AF by 20% to 40%.

Right atrial or biatrial pacing using temporary electrodes attached to the right and left atria is reported to reduce the risk for postoperative AF by 40%.

The following agents have also been demonstrated in randomized studies to reduce the risk for AF after open heart surgery: atorvastatin, which decreases the risk by approximately 60%; hydrocortisone, which decreases the risk by approximately 35%⁶⁰; and colchicine, which decreases the risk by 45%.⁶¹ The main mechanism by which these agents prevent AF is probably an anti-inflammatory effect. Omega-3 PUFAs, which also have an anti-inflammatory effect, reduced the risk for postoperative AF by 43% in one randomized study⁶² but did not reduce the risk in another randomized study.⁶³

Wolff-Parkinson-White Syndrome

Patients with Wolff-Parkinson-White syndrome and an accessory pathway with a short refractory period can experience a very rapid ventricular rate during AF (see Chapters 35 and 37). Ventricular rates higher than 250 to 300 beats/min can result in loss of consciousness or precipitate ventricular fibrillation and cardiac arrest. Patients with Wolff-Parkinson-White syndrome who have AF with a rapid ventricular rate should undergo transthoracic cardioversion if they are hemodynamically unstable. If the patient is hemodynamically stable, intravenous procainamide or ibutilide can be used for pharmacologic cardioversion. Procainamide may be preferable to ibutilide because it blocks accessory pathway conduction and slows the ventricular rate before AF has converted to sinus rhythm. Digitalis and calcium channel antagonists are contraindicated in patients with Wolff-Parkinson-White syndrome and AF. These agents selectively block conduction in the AV node and can result in acceleration of conduction through the accessory pathway.

The preferred therapy for patients with Wolff-Parkinson-White syndrome and AF with a rapid ventricular rate is catheter ablation of the accessory pathway. The efficacy of catheter ablation is 95% for most types of accessory pathways, and the risk for a major complication is very low. AF typically no longer recurs after successful accessory pathway ablation, probably because AF in Wolff-Parkinson-White syndrome is often induced by tachycardia and is a result of AV reciprocating tachycardia.

Heart Failure

AF is a common arrhythmia in patients with heart failure, with a prevalence reported to range from 10% in patients with New York

Heart Association functional class I up to 50% in patients with class IV (see Chapter 25). AF may be the cause of heart failure in patients with nonischemic cardiomyopathy and AF with a rapid ventricular rate. In patients with structural heart disease and preexisting left ventricular dysfunction, AF can worsen the heart failure. The deleterious hemodynamic effects of AF are mediated by a rapid rate or irregular ventricular rate and loss of AV synchrony.

The most appropriate rate-control drugs in patients with heart failure are digitalis and beta blockers. If necessary, amiodarone can also be used for rate control. The only rhythm-control drugs safe to use in patients with heart failure are amiodarone and dofetilide. These are the only two rhythm-control drugs that have been demonstrated to not increase the risk for death in patients with heart failure.

As in other patients with AF, the decision to pursue a rate-control or rhythm-control strategy in patients with heart failure should be individualized. In a multicenter study, patients with AF, heart failure, and a mean left ventricular ejection fraction of 27% were randomly assigned to a rate-control strategy (most commonly digitalis and beta blockers) or a rhythm-control strategy (most often amiodarone).⁶⁴ At 3 years of follow-up, no significant differences were noted in all-cause mortality, cardiovascular mortality, or worsening heart failure, but the hospitalization rate was higher in the rhythm-control group. This study demonstrated no beneficial effect of a rhythm-control strategy on outcomes in patients with heart failure. However, endpoints such as ejection fraction and functional capacity were not examined in the study, and many patients in the rhythm-control arm continued to have AF. It should be noted that the study compared two treatment strategies, not sinus rhythm versus AF with a controlled ventricular rate. The study did not rule out the possibility that sinus rhythm has advantages over AF with a controlled ventricular rate in patients with heart failure.

In another randomized study, patients with AF, heart failure, and an ejection fraction lower than 40% were randomly assigned to rhythm control by catheter ablation or rate control by AV node ablation plus a biventricular pacemaker.⁶⁵ The rate of freedom from AF at 6 months in the AF ablation arm was 71% in the absence of antiarrhythmic drug therapy. The mean ejection fraction improved from approximately 27% to 35% in the AF ablation group and remained unchanged in the AV node ablation group. Functional capacity and quality of life also improved significantly in the AF ablation group, but not in the AV node ablation group. The failure of AV node ablation to improve these parameters is attributable to the fact that the patients had already achieved adequate rate control with drug therapy.

These results suggest that attempts at restoration of sinus rhythm are worthwhile in patients with heart failure and that catheter ablation of AF should be considered if sinus rhythm is not maintained by amiodarone or dofetilide. A rate-control strategy is appropriate for patients who do not respond adequately to amiodarone or dofetilide and either are not suitable candidates for catheter ablation of AF or have had an unsuccessful outcome from ablation. AV node ablation should be reserved for patients whose ventricular rate during AF is not adequately controlled by drug therapy. Because left ventricular dysfunction and heart failure can be aggravated by right ventricular pacing, biventricular pacing should be performed after AV node ablation. The decision to implant a biventricular pacemaker versus a biventricular ICD is based on clinical judgment. If it seems likely that the ejection fraction will remain less than 30% to 35% after optimal heart rate control, a biventricular ICD is appropriate for primary prevention of sudden cardiac death.

Pregnancy

New-onset AF is rare during pregnancy (see Chapter 78), and when it does occur, it is usually in the setting of underlying congenital or valvular heart disease, thyrotoxicosis, or electrolyte abnormalities. In women with paroxysmal AF before pregnancy, the frequency of episodes may or may not increase during pregnancy. Specific recommendations for the management of AF during pregnancy are provided in the Guidelines for Atrial Fibrillation.

FUTURE PERSPECTIVES

The ideal antiarrhythmic drug to prevent AF would affect the atrium only, thereby eliminating the potential for ventricular proarrhythmia. Such drugs are under development and may improve the safety and efficacy of pharmacologic therapy for AF. It is likely that drugs that modify a single channel will not be as effective as those with multiple actions, and it is possible that targeting of non-channel-related functions such as the development of fibrosis will prove useful.

In the past few years, significant progress has been made in the field of catheter ablation of AF, but there is still much room for improvement in efficacy and procedure duration. The failure to create enduring pulmonary vein isolation often accounts for recurrences of AF in patients with paroxysmal AF. The development of new tools for catheter ablation, such as radiofrequency ablation catheters that sense tissue contact force, might improve the ability to safely create transmural lesions, thereby limiting the need for repeated ablation procedures. In patients with persistent AF, a better understanding of AF mechanisms could result in more efficient and successful ablation strategies. The recent demonstration of localized sources of AF (focal impulses and/or atrial rotor) by computed signal analysis in humans represents an important step in this direction.⁵

Several studies have shown that a rhythm-control strategy in patients with AF provides no advantages in outcomes over a rate-control strategy. The results of these studies were most likely influenced by the suboptimal safety and efficacy of the drugs used for rhythm control.

To date, no randomized trials have demonstrated that catheter ablation of AF improves outcomes such as stroke or survival. The ongoing trial CABANA (Catheter Ablation versus Antiarrhythmic Drug Therapy for Atrial Fibrillation) has a primary endpoint of mortality and secondary endpoints of cardiovascular mortality and stroke. If this study shows improved outcomes with AF ablation, it will strengthen the case for rhythm control by ablation.

GUIDELINES

Atrial Fibrillation

Fred Morady and Douglas P. Zipes

Recent updates have been incorporated into the comprehensive guidelines for the management of atrial fibrillation (AF) published in 2006 by the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines.¹ The following classification system was used for recommendations and for the level of evidence on which the recommendations are based:

Class I: conditions for which there is evidence and/or general agreement that the test is useful and effective

Class IIa: weight of evidence or opinion in favor of usefulness/efficacy
Class IIb: usefulness or efficacy less well established by evidence or opinion

Class III: conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Level A: recommendations derived from data from multiple randomized clinical trials

Level B: recommendations derived from a single randomized trial or nonrandomized studies

Level C: recommendations based on the consensus opinion of experts

The guidelines do not necessarily define the standard of care. Management decisions must be individualized on the basis of the particular circumstances of a patient, and in some situations, deviation from the guidelines may be appropriate.

CLASSIFICATION OF ATRIAL FIBRILLATION

The terminology used to classify AF in the guidelines is as follows: *paroxysmal AF* is defined as episodes of AF that last less than 7 days, *persistent AF* is defined as AF that lasts more than 7 days, and *long-standing AF* refers to AF that has been persistent for more than 1 year. These designations are not altered by termination of AF via drug therapy or electrical cardioversion. AF that is resistant to electrical cardioversion is referred to as *permanent AF*. AF is considered recurrent after two or more episodes have occurred.

Some patients with paroxysmal AF occasionally have episodes that are persistent, and vice versa. In this event the AF should be categorized on the basis of the predominant form. Lone AF refers to AF in patients younger than 60 years who do not have structural heart disease or hypertension. AF that is secondary to acute myocardial infarction, cardiac surgery, pericarditis, myocarditis, hyperthyroidism, or an acute pulmonary process is considered separately because the AF often resolves after treatment of the underlying disorder.

MANAGEMENT OF ATRIAL FIBRILLATION

The guidelines address five aspects of the management of AF: pharmacologic rate control; prevention of thromboembolic complications; cardioversion; maintenance of sinus rhythm; and special considerations, including postoperative AF, myocardial infarction,

Wolff-Parkinson-White syndrome, hyperthyroidism, pregnancy, hypertrophic cardiomyopathy, and pulmonary disease.

An important aspect in the management of patients with AF that is not specifically addressed in the guidelines is how to decide on a rate-control strategy versus a rhythm-control strategy. Several clinical trials have demonstrated that pharmacologic rhythm-control and rate-control strategies result in similar outcomes, even in patients with AF who have left ventricular dysfunction and heart failure. On the other hand, a randomized trial of left atrial radiofrequency catheter ablation versus atrioventricular (AV) node ablation and biventricular pacing demonstrated significantly greater improvement in left ventricular function, exercise capacity, and quality of life in patients with heart failure who were treated by ablation. It is possible that the side effects from the drugs used for rhythm control offset the benefits of sinus rhythm. Specific recommendations regarding rhythm-control versus rate-control strategies are difficult to provide because the decision must be individualized on the basis of several factors, including age, symptom severity, functional limitations, patient preference, comorbid conditions, sinus node function, and response to drug therapy.

Pharmacologic Rate Control During Atrial Fibrillation (Table 38G-1)

In addition to specific recommendations on the use of particular drugs for control of the ventricular rate, the guidelines recommend

TABLE 38G-1 ACC/AHA Recommendations for Pharmacologic Rate Control of Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Measurement of the heart rate at rest and control of the rate with pharmacologic agents (in most cases either a beta blocker or nondihydropyridine calcium channel antagonist) are recommended for patients with persistent or permanent AF	B
	In the absence of preexcitation, intravenous administration of beta blockers (esmolol, metoprolol, or propranolol) or nondihydropyridine calcium channel antagonists (verapamil, diltiazem) is recommended to slow the ventricular response to AF in the acute setting, with caution being exercised in patients with hypotension or heart failure	B
	Intravenous administration of digoxin or amiodarone is recommended to control the heart rate in patients with AF and heart failure who do not have an accessory pathway	B
	In patients who experience symptoms related to AF during activity, the adequacy of heart rate control should be assessed during exercise, with pharmacologic treatment being adjusted as necessary to keep the rate in the physiologic range	C
	Digoxin is effective after oral administration to control the heart rate at rest in patients with AF and is indicated for patients with heart failure or left ventricular dysfunction and for sedentary individuals	C
Class IIa (reasonable)	A combination of digoxin and either a beta blocker or nondihydropyridine calcium channel antagonist is reasonable to control the heart rate both at rest and during exercise in patients with AF. The choice of medication should be individualized and the dose modulated to avoid bradycardia	B
	It is reasonable to use ablation of the AV node or accessory pathway to control the heart rate when pharmacologic therapy is insufficient or associated with side effects	B
	Intravenous amiodarone can be useful to control heart rate in patients with AF when other measures are unsuccessful or contraindicated	C
	When electrical cardioversion is not necessary in patients with AF and an accessory pathway, intravenous procainamide or ibutilide is a reasonable alternative	C
Class IIb (may be considered)	When the ventricular rate cannot be adequately controlled both at rest and during exercise in patients with AF by a beta blocker, nondihydropyridine calcium channel antagonist, or digoxin, alone or in combination, oral amiodarone may be administered to control the heart rate	C
	Intravenous procainamide, disopyramide, ibutilide, or amiodarone may be considered for hemodynamically stable patients with AF involving conduction over an accessory pathway	B
	When the rate cannot be controlled with pharmacologic agents or tachycardia-mediated cardiomyopathy is suspected, catheter-directed ablation of the AV node may be considered in patients with AF to control the heart rate	C
Class III (not indicated)	Strict rate control (<80 beats/min at rest or <110 beats/min during a 6-minute walk) is not more beneficial than a resting rate of <110 beats/min in asymptomatic patients with persistent AF and an ejection fraction >40%, although uncontrolled tachycardia can lead to reversible left ventricular dysfunction over time	B
	Digitalis should not be used as the sole agent to control the rate of ventricular response in patients with paroxysmal AF	B
	Catheter ablation of the AV node should not be attempted without a prior trial of medication to control the ventricular rate in patients with AF	C
	In patients with decompensated heart failure and AF, intravenous administration of a nondihydropyridine calcium channel antagonist may exacerbate the hemodynamic compromise and is not recommended	C
	Intravenous administration of digitalis glycosides or nondihydropyridine calcium channel antagonists to patients with AF and a preexcitation syndrome may paradoxically accelerate the ventricular response and is not recommended	C

that the effects of drug therapy on ventricular rate be measured at rest and during exercise to ensure adequate heart rate control. The criteria used for rate control are rates of 60 to 80 beats/min at rest and 90 to 115 beats/min during moderate exercise.

A new recommendation as of 2011 is that a resting rate of less than 110 beats/min is a reasonable rate-control target in patients with persistent AF and no arrhythmia-related symptoms who have an ejection fraction higher than 40%. However, the guidelines caution that tachycardia can result in a decline in left ventricular function over time.

Digoxin is much less effective for control of the ventricular rate during exercise than at rest and is indicated for patients with heart failure or left ventricular dysfunction and for sedentary patients. A combination of digoxin and either a beta blocker or a nondihydropyridine calcium channel antagonist is appropriate to control the rate at rest and during exercise. The guidelines recommend that digoxin be used as the sole agent for rate control in patients with paroxysmal AF. Catheter ablation of the AV node should be reserved for patients whose ventricular rate cannot be adequately controlled by drug therapy because of either inefficacy or drug intolerance.

Prevention of Thromboembolism (Table 38G-2)

The 2006 guidelines recommend antithrombotic therapy with either aspirin or a vitamin K antagonist such as warfarin for all patients with

AF except those who have lone AF or contraindications. An updated recommendation as of 2011 is that the direct thrombin inhibitor dabigatran is a useful alternative to warfarin for prevention of stroke or embolism in patients with AF. The choice between aspirin and an anticoagulant is based on the patient's risk profile. Factors associated with the highest risk for thromboembolism are a previous thromboembolic event and rheumatic mitral stenosis, and warfarin or dabigatran is recommended for patients with one of these risk factors. Risk factors associated with a moderate risk for thromboembolism are 75 years of age or older, hypertension, heart failure, ejection fraction of 35% or lower, and diabetes. Aspirin is recommended if none of these risk factors are present, and an anticoagulant is recommended for patients with one or more of these risk factors. In patients with only one of the moderate risk factors, either aspirin or an anticoagulant is reasonable, and the choice should be individualized.

Rivaroxaban was approved by the Food and Drug Administration in 2011 after publication of the updated guidelines dealing with dabigatran. It seems appropriate to generalize the recommendations regarding dabigatran to the factor Xa inhibitor rivaroxaban.

Another update to the 2006 guidelines addresses combination therapy with aspirin and clopidogrel. This combination has been demonstrated to be less effective than warfarin for preventing strokes but more effective than aspirin by itself. The guidelines now recommend that aspirin plus clopidogrel be considered for prevention of stroke in patients who cannot tolerate or refuse to take an oral anticoagulant.

TABLE 38G-2 ACC/AHA Recommendations for Prevention of Thromboembolism in Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Antithrombotic therapy to prevent thromboembolism is recommended for all patients with AF, except those with lone AF or contraindications	A
	Selection of the antithrombotic agent should be based on the absolute risks for stroke and bleeding and the relative risk and benefit in a given patient	A
	For patients without mechanical heart valves at high risk for stroke, chronic oral anticoagulant therapy with a vitamin K antagonist is recommended in a dose adjusted to achieve the target intensity INR of 2.0 to 3.0 unless contraindicated. Factors associated with highest risk for stroke in patients with AF are previous thromboembolism (stroke, transient ischemic attack, or systemic embolism) and rheumatic mitral stenosis	A
	Anticoagulation with a vitamin K antagonist is recommended for patients with more than one moderate risk factor. Such factors include age 75 years or older, hypertension, heart failure, impaired left ventricular systolic function (ejection fraction \leq 35% or fractional shortening $<$ 25%), and diabetes mellitus	A
	The INR should be determined at least weekly during initiation of therapy and monthly when anticoagulation is stable	A
	Dabigatran is a useful alternative to warfarin in patients with AF and risk factors for stroke who do not have a prosthetic heart valve or significant valve disease, a creatinine clearance $<$ 15 mL/min, or advanced liver disease	B
	Aspirin, 81 to 325 mg daily, is recommended as an alternative to vitamin K antagonists in low-risk patients or in those with contraindications to oral anticoagulation	A
	For patients with AF who have mechanical heart valves, the target intensity of anticoagulation should be based on the type of prosthesis while maintaining an INR of at least 2.5	B
	Antithrombotic therapy is recommended for patients with atrial flutter as for those with AF	C
Class IIa (reasonable)	For primary prevention of thromboembolism in patients with nonvalvular AF who have just one of the following validated risk factors, antithrombotic therapy with either aspirin or a vitamin K antagonist is reasonable based on an assessment of the risk for bleeding complications, ability to safely sustain adjusted chronic anticoagulation, and the patient's preferences: age 75 years or older (especially in women), hypertension, heart failure, impaired left ventricular function, or diabetes mellitus	A
	For patients with nonvalvular AF who have one or more of the following less well validated risk factors, antithrombotic therapy with either aspirin or a vitamin K antagonist is reasonable for prevention of thromboembolism: age 65 to 74 years, female sex, or coronary artery disease. The choice of agent should be based on the risk for bleeding complications, ability to sustain adjusted chronic anticoagulation, and the patient's preferences	B
	It is reasonable to select antithrombotic therapy by the same criteria irrespective of the pattern (i.e., paroxysmal, persistent, or permanent) of AF	B
	In patients with AF who do not have mechanical prosthetic heart valves, it is reasonable to interrupt anticoagulation for up to 1 week without substituting heparin for surgical or diagnostic procedures that carry a risk for bleeding	C
	It is reasonable to reevaluate the need for anticoagulation at regular intervals	C

Continued

**TABLE 38G-2 ACC/AHA Recommendations for Prevention of Thromboembolism in Atrial Fibrillation—cont'd**

CLASS	INDICATION	LEVEL OF EVIDENCE
Class IIb (may be considered)	In patients 75 years or older at increased risk for bleeding but without frank contraindications to oral anticoagulant therapy and in other patients with moderate risk factors for thromboembolism who are unable to safely tolerate anticoagulation at the standard intensity of an INR of 2.0 to 3.0, a lower INR target of 2.0 (range, 1.6 to 2.5) may be considered for prevention of ischemic stroke and systemic embolism	C
	When surgical procedures require interruption of oral anticoagulant therapy for longer than 1 week in high-risk patients, unfractionated heparin may be administered or low-molecular-weight heparin given by subcutaneous injection, although the efficacy of these alternatives in this situation is uncertain	C
	After percutaneous coronary intervention or revascularization surgery in patients with AF, low-dose aspirin (<100 mg/day) and/or clopidogrel (75 mg/day) may be given concurrently with anticoagulation to prevent myocardial ischemic events, but these strategies have not been thoroughly evaluated and are associated with an increased risk for bleeding	C
	In patients undergoing percutaneous coronary intervention, anticoagulation may be interrupted to prevent bleeding at the site of peripheral arterial puncture, but the vitamin K antagonist should be resumed as soon as possible after the procedure and the dose adjusted to achieve an INR in the therapeutic range. Aspirin may be given temporarily during the hiatus, but the maintenance regimen should then consist of the combination of clopidogrel, 75 mg daily, plus warfarin (INR, 2.0 to 3.0). Clopidogrel should be given for a minimum of 1 month after implantation of a bare-metal stent, at least 3 months for a sirolimus-eluting stent, at least 6 months for a paclitaxel-eluting stent, and 12 months or longer in selected patients, following which warfarin may be continued as monotherapy in the absence of a subsequent coronary event. When warfarin is given in combination with clopidogrel or low-dose aspirin, the dose intensity must be carefully regulated	C
	In patients with AF younger than 60 years without heart disease or risk factors for thromboembolism (lone AF), the risk for thromboembolism is low without treatment, and the effectiveness of aspirin for primary prevention of stroke relative to the risk for bleeding has not been established	C
	In patients with AF who sustain an ischemic stroke or systemic embolism during treatment with low-intensity anticoagulation (INR, 2.0 to 3.0), rather than add an antiplatelet agent, it may be reasonable to raise the intensity of the anticoagulation to a maximum target INR of 3.0 to 3.5	C
Class III (not indicated)	Clopidogrel plus aspirin may be considered in patients who cannot tolerate or who refuse an oral anticoagulant	B
	Long-term anticoagulation with a vitamin K antagonist is not recommended for primary prevention of stroke in patients younger than 60 years without heart disease (lone AF) or any risk factors for thromboembolism	C

INR = international normalized ratio.

Cardioversion of Atrial Fibrillation (Table 38G-3)

The first-line drugs recommended for cardioversion are flecainide, dofetilide, propafenone, and ibutilide. Amiodarone is considered a reasonable option. The guidelines state that digoxin and sotalol may be harmful when they are used for cardioversion and recommend against use of these agents for that purpose.

Direct-current cardioversion is recommended when the ventricular rate is rapid and does not respond quickly to drug therapy in patients with myocardial ischemia, hypotension, or heart failure and in patients with Wolff-Parkinson-White syndrome and AF with a very rapid rate or hemodynamic instability. If AF recurs early after direct-current cardioversion, repeated cardioversion is recommended after treatment with an antiarrhythmic drug.

If AF has been present for longer than 48 hours or if the duration is unknown, anticoagulation with warfarin and an international normalized ratio (INR) of 2 to 3 is recommended for 3 or more weeks before cardioversion, whether pharmacologic or electrical, and for 4 weeks afterward. It is reasonable to presume that dabigatran and rivaroxaban are suitable alternatives to warfarin.

When cardioversion is performed within 48 hours of the onset of AF, anticoagulation before and after cardioversion may be based on the patient's risk profile.

In patients with AF lasting longer than 48 hours or in whom the duration is unknown, an alternative to anticoagulation for 3 or more weeks before cardioversion is to perform transesophageal echocardiography, to anticoagulate the patient with heparin, to initiate oral anticoagulation, and to proceed with immediate cardioversion if no thrombi are present in the left atrium or left atrial appendage. In

patients receiving warfarin, heparin should be continued until the INR is 2, and oral anticoagulation with an INR of 2 to 3 should be continued for 4 or more weeks. In patients treated with dabigatran or rivaroxaban, heparin can be discontinued 3 to 4 hours after the first oral dose. As with warfarin, anticoagulation therapy should be continued for 4 or more weeks.

Maintenance of Sinus Rhythm (Table 38G-4)

A reasonable outcome of antiarrhythmic drug therapy is infrequent recurrences of well-tolerated AF. Initiation of a rhythm-control medication is reasonable on an outpatient basis in patients without heart disease when the medication is well tolerated. The updated guidelines now recommend dronedarone as being a reasonable option in patients with paroxysmal AF or after conversion of persistent AF. The guidelines recommend catheter ablation of symptomatic paroxysmal AF for patients who have failed treatment with an antiarrhythmic drug and have little or no left atrial enlargement and normal or mildly reduced left ventricular function.

Special Considerations (Table 38G-5) Postoperative Atrial Fibrillation

The guidelines recommend prophylactic treatment with an oral beta blocker to prevent postoperative AF in patients undergoing cardiac surgery. Preoperative amiodarone is also considered to be appropriate prophylactic therapy to prevent postoperative AF. Use of cardioversion, rhythm-control medications, and antithrombotic medication should be based on the same considerations as in nonsurgical patients.

TABLE 38G-3 ACC/AHA Recommendations for Cardioversion of Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Pharmacologic Cardioversion		
Class I (indicated)	Administration of flecainide, dofetilide, propafenone, or ibutilide is recommended for pharmacologic cardioversion of AF	A
Class IIa (reasonable)	Administration of amiodarone is a reasonable option for pharmacologic cardioversion of AF	A
	A single oral bolus dose of propafenone or flecainide ("pill-in-the-pocket" approach) can be administered to terminate persistent AF outside the hospital once treatment has proved safe in the hospital for selected patients without sinus or AV node dysfunction, bundle branch block, prolongation of the QT interval, Brugada syndrome, or structural heart disease. Before antiarrhythmic medication is initiated, a beta blocker or nondihydropyridine calcium channel antagonist should be given to prevent rapid AV conduction in the event that atrial flutter occurs	C
	Administration of amiodarone can be beneficial on an outpatient basis in patients with paroxysmal or persistent AF when rapid restoration of sinus rhythm is not deemed necessary	C
Class IIb (may be considered)	Administration of quinidine or procainamide might be considered for pharmacologic cardioversion of AF, but the usefulness of these agents is not well established	C
Class III (not indicated)	Digoxin and sotalol may be harmful when used for pharmacologic cardioversion of AF and are not recommended	A
	Quinidine, procainamide, disopyramide, and dofetilide should not be started out of the hospital for conversion of AF to sinus rhythm	B
Direct-Current Cardioversion		
Class I (indicated)	When a rapid ventricular response to pharmacologic measures does not occur in patients with AF and ongoing myocardial ischemia, symptomatic hypotension, angina, or heart failure, immediate R wave–synchronized direct-current cardioversion is recommended	C
	Immediate direct-current cardioversion is recommended for patients with AF involving preexcitation when very rapid tachycardia or hemodynamic instability occurs	B
	Cardioversion is recommended in patients without hemodynamic instability when symptoms of AF are unacceptable to the patient. In case of early relapse of AF after cardioversion, repeated attempts at direct-current cardioversion may be made after administration of antiarrhythmic medication	C
Class IIa (reasonable)	Direct-current cardioversion can be useful to restore sinus rhythm as part of a long-term management strategy for patients with AF	B
	The patient's preference is a reasonable consideration in the selection of infrequently repeated cardioversions for the management of symptomatic or recurrent AF	C
Class III (not indicated)	Frequent repetition of direct-current cardioversion is not recommended for patients who have relatively short periods of sinus rhythm between relapses of AF after multiple cardioversion procedures despite prophylactic antiarrhythmic drug therapy	C
	Electrical cardioversion is contraindicated in patients with digitalis toxicity or hypokalemia	C
Pharmacologic Enhancement of Direct-Current Cardioversion		
Class IIa (reasonable)	Pretreatment with amiodarone, flecainide, ibutilide, propafenone, or sotalol can be useful to enhance the success of direct-current cardioversion and to prevent recurrent AF	B
	In patients in whom AF recurs after successful cardioversion, it can be useful to repeat the procedure after prophylactic administration of antiarrhythmic medication	C
Class IIb (may be considered))	For patients with persistent AF, administration of beta blockers, disopyramide, diltiazem, dofetilide, procainamide, or verapamil may be considered, although the efficacy of these agents in enhancing the success of direct-current cardioversion or in preventing early recurrence of AF is uncertain	C
	Out-of-hospital initiation of antiarrhythmic medications may be considered in patients without heart disease to enhance the success of cardioversion of AF	C
	Out-of-hospital administration of antiarrhythmic medications may be considered to enhance the success of cardioversion of AF in patients with certain forms of heart disease once the safety of the drug has been verified for the patient	C
Prevention of Thromboembolism in Patients with Atrial Fibrillation Undergoing Cardioversion		
Class I (indicated)	For patients with AF lasting 48 hours or longer or when the duration of AF is unknown, anticoagulation (INR of 2.0 to 3.0) is recommended for at least 3 weeks before and 4 weeks after cardioversion, regardless of the method (electrical or pharmacologic) used to restore sinus rhythm	B
	For patients with AF lasting longer than 48 hours who require immediate cardioversion because of hemodynamic instability, heparin should be administered concurrently (unless contraindicated) via an initial intravenous bolus injection, followed by a continuous infusion in a dose adjusted to prolong the activated partial thromboplastin time to 1.5 to 2 times the reference control value. Thereafter, oral anticoagulation (INR of 2.0 to 3.0) should be provided for at least 4 weeks, as for patients undergoing elective cardioversion. Limited data support subcutaneous administration of low-molecular-weight heparin for this indication	C
	For patients with AF of less than a 48-hour duration associated with hemodynamic instability (angina pectoris, myocardial infarction, shock, or pulmonary edema), cardioversion should be performed immediately, without delay for initiation of anticoagulation	C

Continued

**TABLE 38G-3 ACC/AHA Recommendations for Cardioversion of Atrial Fibrillation—cont'd**

CLASS	INDICATION	LEVEL OF EVIDENCE
Class IIa (reasonable)	During the 48 hours after the onset of AF, the need for anticoagulation before and after cardioversion may be based on the patient's risk for thromboembolism	C
	As an alternative to anticoagulation before cardioversion of AF, it is reasonable to perform transesophageal echocardiography to search for a thrombus in the left atrium or left atrial appendage	B
	a. For patients with no identifiable thrombus, cardioversion is reasonable immediately after anticoagulation with unfractionated heparin (e.g., initiated by intravenous bolus injection and an infusion continued at a dose adjusted to prolong the activated partial thromboplastin time to 1.5 to 2 times the control value until oral anticoagulation has been established with an oral vitamin K antagonist [e.g., warfarin] as evidenced by an INR ≥ 2.0)	B
	Thereafter, continuation of oral anticoagulation (INR of 2.0 to 3.0) is reasonable for a total anticoagulation period of at least 4 weeks, as for patients undergoing elective cardioversion	B
	Limited data are available to support the subcutaneous administration of a low-molecular-weight heparin for this indication	C
	b. For patients in whom a thrombus is identified by transesophageal echocardiography, oral anticoagulation (INR of 2.0 to 3.0) is reasonable for at least 3 weeks before and 4 weeks after restoration of sinus rhythm, and a longer period of anticoagulation may be appropriate even after apparently successful cardioversion because the risk for thromboembolism often remains elevated in such cases	C
	For patients with atrial flutter undergoing cardioversion, anticoagulation can be beneficial according to the recommendations as for patients with AF	C

TABLE 38G-4 ACC/AHA Recommendations for Maintenance of Sinus Rhythm in Patients with Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Before initiation of antiarrhythmic drug therapy, treatment of precipitating or reversible causes of AF is recommended	C
	Catheter ablation by an experienced operator is useful in selected patients with symptomatic paroxysmal AF who have failed treatment with an antiarrhythmic drug and have a normal or mildly dilated left atrium and normal or mildly reduced left ventricular function	A
Class IIa (reasonable)	Pharmacologic therapy can be useful in patients with AF to maintain sinus rhythm and to prevent tachycardia-induced cardiomyopathy	C
	Infrequent, well-tolerated recurrence of AF is reasonable as a successful outcome of antiarrhythmic drug therapy	C
	Outpatient initiation of antiarrhythmic drug therapy is reasonable in patients with AF who have no associated heart disease when the agent is well tolerated	C
	In patients with lone AF without structural heart disease, initiation of propafenone or flecainide can be beneficial on an outpatient basis in patients with paroxysmal AF who are in sinus rhythm at the time of drug initiation	B
	Sotalol can be beneficial in outpatients in sinus rhythm with little or no heart disease who are prone to paroxysmal AF if the baseline uncorrected QT interval is shorter than 460 msec, serum electrolyte values are normal, and risk factors associated with class III drug-related proarrhythmia are not present	C
	Catheter ablation is a reasonable option for the treatment of symptomatic persistent AF	A
Class IIb (may be considered)	Catheter ablation may be reasonable for patients with symptomatic paroxysmal AF and significant left atrial dilation or significant left ventricular dysfunction	A
Class III (not indicated)	Antiarrhythmic therapy with a particular drug is not recommended for maintenance of sinus rhythm in patients with AF who have well-defined risk factors for proarrhythmia with that agent	A
	Pharmacologic therapy is not recommended for maintenance of sinus rhythm in patients with advanced sinus node disease or AV node dysfunction unless they have a functioning electronic cardiac pacemaker	C

Acute Myocardial Infarction

Electrical cardioversion is recommended for patients with hemodynamic compromise or ongoing ischemia or when adequate rate control cannot be achieved with drug therapy. The guidelines recommend intravenous amiodarone or digitalis to slow the ventricular rate in patients and to improve left ventricular function in those with acute myocardial infarction. In patients without left ventricular dysfunction, bronchospasm, or AV block, an intravenous beta blocker or nondihydropyridine calcium channel antagonist is recommended for rate control.

Atrial Fibrillation in Wolff-Parkinson-White Syndrome

Catheter ablation of the accessory pathway is recommended for patients with symptomatic AF and Wolff-Parkinson-White syndrome. Immediate electrical cardioversion is recommended for those with AF and a rapid ventricular rate and hemodynamic instability. If the patient is hemodynamically stable, intravenous procainamide or ibutilide is recommended for pharmacologic conversion of AF. Intravenous digitalis and nondihydropyridine calcium channel antagonists should be avoided in patients with ventricular preexcitation during AF.

TABLE 38G-5 ACC/AHA Recommendations for Special Considerations in Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Postoperative Atrial Fibrillation		
Class I (indicated)	Unless contraindicated, treatment with an oral beta blocker to prevent postoperative AF is recommended for patients undergoing cardiac surgery	A
	Administration of AV nodal blocking agents is recommended to achieve rate control in patients in whom AF develops postoperatively	B
Class IIa (reasonable)	Preoperative administration of amiodarone reduces the incidence of AF in patients undergoing cardiac surgery and represents appropriate prophylactic therapy for patients at high risk for postoperative AF	A
	It is reasonable to restore sinus rhythm by pharmacologic cardioversion with ibutilide or direct-current cardioversion in patients in whom AF develops postoperatively, as advised for nonsurgical patients	B
	It is reasonable to administer antiarrhythmic medications in an attempt to maintain sinus rhythm in patients with recurrent or refractory postoperative AF, as recommended for other patients in whom AF develops	B
	It is reasonable to administer antithrombotic medication in patients in whom AF develops postoperatively, as recommended for nonsurgical patients	B
Class IIb (may be considered)	Prophylactic administration of sotalol may be considered for patients at risk for the development of AF after cardiac surgery	B
Acute Myocardial Infarction		
Class I (indicated)	Direct-current cardioversion is recommended for patients with severe hemodynamic compromise or intractable ischemia or when adequate rate control cannot be achieved with pharmacologic agents in patients with acute myocardial infarction and AF	C
	Intravenous administration of amiodarone is recommended to slow a rapid ventricular response to AF and to improve left ventricular function in patients with acute myocardial infarction	C
	Intravenous beta blockers and nondihydropyridine calcium channel antagonists are recommended to slow a rapid ventricular response to AF in patients with acute myocardial infarction who do not display clinical left ventricular dysfunction, bronchospasm, or AV block	C
	For patients with AF and acute myocardial infarction, administration of unfractionated heparin by either continuous intravenous infusion or intermittent subcutaneous injection is recommended in a dose sufficient to prolong the activated partial thromboplastin time to 1.5 to 2 times the control value, unless contraindications to anticoagulation exist	C
Class IIa (reasonable)	Intravenous administration of digitalis is reasonable to slow a rapid ventricular response and to improve left ventricular function in patients with acute myocardial infarction and AF associated with severe left ventricular dysfunction and heart failure	C
Class III (not indicated)	Administration of class IC antiarrhythmic drugs is not recommended in patients with AF in the setting of acute myocardial infarction	C
Management of Atrial Fibrillation Associated with Wolff-Parkinson-White (WPW) Preexcitation Syndrome		
Class I (indicated)	Catheter ablation of the accessory pathway is recommended for symptomatic patients with AF who have WPW syndrome, particularly those with syncope secondary to a rapid heart rate or those with a short bypass tract refractory period	B
	Immediate direct-current cardioversion is recommended to prevent ventricular fibrillation in patients with a short anterograde bypass tract refractory period in whom AF occurs with a rapid ventricular response associated with hemodynamic instability	B
	Intravenous procainamide or ibutilide is recommended to restore sinus rhythm in patients with WPW syndrome in whom AF occurs without hemodynamic instability in association with a wide QRS complex on the electrocardiogram (≥ 120 -msec duration) or with a rapid preexcited ventricular response	C
Class IIa (reasonable)	Intravenous flecainide or direct-current cardioversion is reasonable when very rapid ventricular rates occur in patients with AF involving conduction over an accessory pathway	B
Class IIb (may be considered)	It may be reasonable to administer intravenous quinidine, procainamide, disopyramide, ibutilide, or amiodarone to hemodynamically stable patients with AF involving conduction over an accessory pathway	B
Class III (not indicated)	Intravenous administration of digitalis glycosides or nondihydropyridine calcium channel antagonists is not recommended in patients with WPW syndrome who have preexcited ventricular activation during AF	B
Hyperthyroidism		
Class I (indicated)	Administration of a beta blocker is recommended to control the rate of ventricular response in patients with AF complicating thyrotoxicosis, unless contraindicated	B
	In circumstances in which a beta blocker cannot be used, administration of a nondihydropyridine calcium channel antagonist (diltiazem or verapamil) is recommended to control the ventricular rate in patients with AF and thyrotoxicosis	B
	In patients with AF associated with thyrotoxicosis, oral anticoagulation (INR of 2.0 to 3.0) is recommended to prevent thromboembolism, as recommended for AF patients with other risk factors for stroke	C
	Once a euthyroid state is restored, recommendations for antithrombotic prophylaxis are the same as for patients without hyperthyroidism	C

Continued

**TABLE 38G-5 ACC/AHA Recommendations for Special Considerations in Atrial Fibrillation—cont'd**

CLASS	INDICATION	LEVEL OF EVIDENCE
Management of Atrial Fibrillation During Pregnancy		
Class I (indicated)	Digoxin, a beta blocker, or a nondihydropyridine calcium channel antagonist is recommended to control the rate of ventricular response in pregnant patients with AF	C
	Direct-current cardioversion is recommended in pregnant patients who become hemodynamically unstable because of AF	C
	Protection against thromboembolism is recommended throughout pregnancy for all patients with AF (except those with lone AF and/or low thromboembolic risk). Therapy (anticoagulant or aspirin) should be chosen according to the stage of pregnancy	C
Class IIb (may be considered)	Administration of heparin may be considered during the first trimester and last month of pregnancy for patients with AF and risk factors for thromboembolism. Unfractionated heparin may be administered either by continuous intravenous infusion in a dose sufficient to prolong the activated partial thromboplastin time to 1.5 to 2 times the control value or by intermittent subcutaneous injection in a dose of 10,000 to 20,000 units every 12 hours, adjusted to prolong the midinterval (6 hours after injection) activated partial thromboplastin time to 1.5 times control	B
	Despite the limited data available, subcutaneous administration of low-molecular-weight heparin may be considered during the first trimester and last month of pregnancy for patients with AF and risk factors for thromboembolism	C
	Administration of an oral anticoagulant may be considered during the second trimester for pregnant patients with AF and high thromboembolic risk	C
	Administration of quinidine or procainamide may be considered to achieve pharmacologic cardioversion in hemodynamically stable patients in whom AF develops during pregnancy	C
Management of Atrial Fibrillation in Patients with Hypertrophic Cardiomyopathy (HCM)		
Class I (indicated)	Oral anticoagulation (INR of 2.0 to 3.0) is recommended in patients with HCM in whom AF develops, as for other patients at high risk for thromboembolism	B
Class IIa (may be considered)	Antiarrhythmic medications can be useful to prevent recurrent AF in patients with HCM. The data available are insufficient to recommend one agent over another in this situation, but (1) disopyramide combined with a beta blocker or nondihydropyridine calcium channel antagonist or (2) amiodarone alone is generally preferred	C
Management of Atrial Fibrillation in Patients with Pulmonary Disease		
Class I (indicated)	Correction of hypoxemia and acidosis is the recommended primary therapeutic measure for patients in whom AF develops during an acute pulmonary illness or exacerbation of chronic pulmonary disease	C
	A nondihydropyridine calcium channel antagonist (diltiazem or verapamil) is recommended to control the ventricular rate in patients with obstructive pulmonary disease in whom AF develops	C
	Direct-current cardioversion should be attempted in patients with pulmonary disease who become hemodynamically unstable as a consequence of AF	C
Class III (not indicated)	Theophylline and beta-adrenergic agonist agents are not recommended for patients with bronchospastic lung disease in whom AF develops	C
	Beta blockers, sotalol, propafenone, and adenosine are not recommended in patients with obstructive lung disease in whom AF develops	C

Hyperthyroidism

The guidelines recommend a beta blocker as first-line therapy for rate control in patients with AF and thyrotoxicosis. If a beta blocker cannot be used, verapamil or diltiazem should be used for rate control. Recommendations for therapy to prevent thromboembolic complications are the same as for patients without hyperthyroidism.

Atrial Fibrillation during Pregnancy

The guidelines recommend digoxin, a beta blocker, or a nondihydropyridine calcium channel antagonist for rate control of AF during pregnancy. Direct-current cardioversion is recommended in hemodynamically unstable patients.

Except in patients with a low-risk profile, either aspirin or an anticoagulant is recommended for prevention of thromboembolic complications, depending on the stage of pregnancy (see Chapter 82). Unfractionated or low-molecular-weight heparin can be considered during the first trimester and last month of pregnancy in patients with risk factors for thromboembolism, and an oral anticoagulant can be considered during the second trimester in patients at high risk for thromboembolism.

When AF occurs during pregnancy, quinidine or procainamide can be considered for pharmacologic cardioversion in hemodynamically stable patients.

Hypertrophic Cardiomyopathy

The guidelines point out that data are not adequate to determine the best rhythm-control medication to use for AF in the setting of hypertrophic cardiomyopathy. The preferred therapy is either disopyramide plus a beta blocker, verapamil, or diltiazem for rate control or amiodarone by itself.

Pulmonary Disease

The primary therapy for AF in the setting of an acute pulmonary illness or exacerbation of chronic pulmonary disease should be correction of hypoxemia and acidosis. Verapamil or diltiazem is recommended for rate control in patients with obstructive pulmonary disease. Theophylline and beta-adrenergic agonists are not recommended in patients with bronchospastic disease, and beta blockers, sotalol, propafenone, and adenosine are not recommended in patients with obstructive lung disease.

PERSPECTIVE

Sudden cardiac death (SCD) is a major public health problem because of its frequency and demographics. With numeric estimates in the range of 300,000 to 375,000 deaths per year in the United States alone, it accounts for half of all cardiovascular deaths. Approximately 50% of all SCDs are unexpected first expressions of a cardiac disorder, often striking during the victim's productive years. Despite recognition of an association between forewarning symptoms of chest pain or syncope and SCD dating to Hippocrates around 400 BC, the description of a "shrunken and withered" artery to the heart in a victim of SCD in the late 1490s by Da Vinci, and an epidemiologic survey in Rome by Lancisi at the request of Pope Clement XI in 1706, advances in prediction, prevention, and management of unexpected cardiac arrest and SCD did not begin to emerge until 50 years ago. It is anticipated that the major insights into causes, pathophysiology, and preventive and management strategies developed during the past few decades, described in this chapter, will continue to evolve.

DEFINITIONS

SCD is natural death from cardiac causes heralded by abrupt loss of consciousness within 1 hour of the onset of an acute change in cardiovascular status (**Table 39-1**). Preexisting heart disease may or may not have been known to be present, but the time and mode of death are unexpected. This definition incorporates the key elements of natural, rapid, and unexpected. It consolidates previous definitions that have conflicted, mainly because the most useful operational definition of SCD in the past differed for clinicians, cardiovascular epidemiologists, pathologists, and scientists attempting to define pathophysiologic mechanisms. As the epidemiology, clinical expression, causes, and mechanisms began to be understood, these differences merged.

To satisfy clinical, scientific, legal, and social considerations, four temporal elements must be considered: (1) prodromes, (2) onset, (3) cardiac arrest, and (4) biologic death (**Fig. 39-1**). Because the proximate cause of SCD is an abrupt disturbance in cardiovascular function followed by loss of consciousness, any definition must recognize the brief time interval between onset of the mechanism directly responsible for cardiac arrest and the consequent loss of blood flow. Therefore the 1-hour definition, which primarily refers to the duration of the "terminal event," defines the interval between the onset of symptoms signaling the pathophysiologic disturbance leading to cardiac arrest and the onset of the cardiac arrest itself.

Prodromes, occurring weeks or months before an event, are not sensitive or specific predictors of an impending event, but premonitory signs and symptoms, which can occur during the days or weeks before cardiac arrest, may be more specific for imminent cardiac arrest when they begin abruptly. Sudden onset of chest pain, dyspnea, or palpitations and other symptoms of arrhythmias often precede the onset of cardiac arrest and define the 1-hour onset of the terminal event that brackets the cardiac arrest. The fourth element, biologic death, was an immediate consequence of cardiac arrest in the past and usually occurred within minutes. However, the generally accepted clinical-pathophysiologic definition of up to 1 hour between onset of the terminal event and biologic death requires qualifications for specific circumstances. For example, since the development of community-based interventions and life support systems, patients may now remain biologically alive for a long period after the onset of a pathophysiologic process that has caused irreversible damage and will ultimately lead to death. In this circumstance, the causative pathophysiologic and clinical event is the cardiac arrest itself rather than the factors responsible for the delayed biologic death. Thus death remains defined biologically, legally, and literally as an absolute and irreversible event timed to cessation of all biologic functions, but most studies link the

TABLE 39-1 Terms Related to Sudden Cardiac Death

TERM	DEFINITION	QUALIFIERS	MECHANISMS
Sudden cardiac death	Sudden, irreversible cessation of all biologic functions	None	—
Cardiac arrest	Abrupt cessation of cardiac mechanical function, which may be reversible with prompt intervention but will lead to death in its absence	Rare spontaneous reversions; the likelihood of successful intervention is related to the mechanism of arrest, clinical setting, and prompt return of circulation	Ventricular fibrillation, ventricular tachycardia, asystole, bradycardia, pulseless electrical activity, mechanical factors
Cardiovascular collapse	Sudden loss of effective blood flow because of cardiac and/or peripheral vascular factors that may reverse spontaneously (e.g., neurocardiogenic syncope, vasovagal syncope) or require interventions (e.g., cardiac arrest)	Nonspecific term; includes cardiac arrest and its consequences and transient non-life-threatening conditions that usually revert spontaneously	Same as cardiac arrest, plus vasodepressor-induced syncope or other causes of transient loss of blood flow

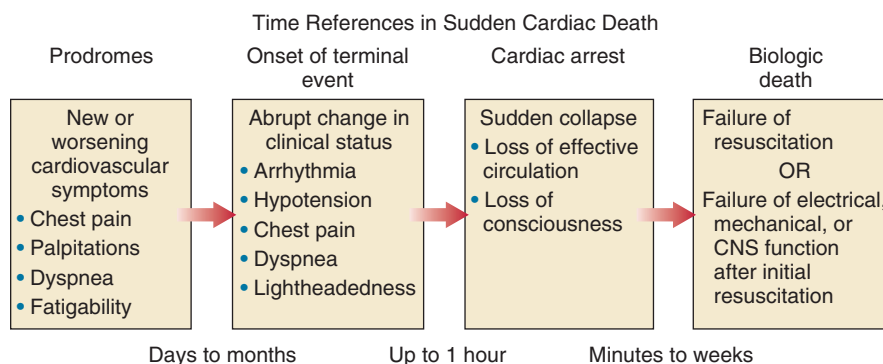

FIGURE 39-1 Sudden cardiac death viewed from four temporal perspectives: (1) prodromes, (2) onset of the terminal event, (3) cardiac arrest, and (4) progression to biologic death. Individual variability of the components influences clinical expression. Some victims experience no prodromes, with onset leading almost instantaneously to cardiac arrest; others may have an onset that lasts up to 1 hour before clinical arrest. Other patients may live days to weeks after the cardiac arrest before biologic death, often because of irreversible brain damage and dependence on life support. These factors influence interpretation of the 1-hour definition. The two most relevant clinical factors are onset of the terminal event and the clinical cardiac arrest itself; legal and social considerations focus on the time of biologic death. CNS = central nervous system.

definition of SCD to the cardiac arrest rather than to a biologic death that occurs during hospitalization after cardiac arrest or within 30 days. Finally, forensic pathologists studying unwitnessed deaths continue to use the definition of sudden death for a person known to be alive and functioning normally 24 hours before, and this remains appropriate within obvious limits.

EPIDEMIOLOGY

Epidemiologic Overview

Epidemiologic studies of SCD are difficult to interpret for both theoretical and practical reasons. There are persisting inconsistencies about the definition and challenges in accessing data and adjudicating individual cases in data sets, in determining pathophysiologic mechanisms, and in making distinctions between population risk and individual risk.¹ In addition, the fact that sudden cardiac arrest (SCA) leading to SCD has short-term dynamics superimposed on a long-term static or dynamic substrate introduces unusual epidemiologic complexities, including long-term risk prediction based on the evolution of atherogenesis, myocardial hypertrophy, and ventricular muscle dysfunction over time and modulation by transient (short-term) variables such as ischemia, hemodynamic shifts, atherosclerotic plaque disruption and thrombosis, and autonomic variations. The differences between chronic disease evolution and transient events call for different forms of epidemiologic modeling (Table 39-2A). Furthermore, the emerging field of genetic epidemiology adds another dimension for study, and there is a need for focusing on *interventional epidemiology*, a term coined to define the population dynamics of therapeutic outcomes.

In reference to risk for SCD from coronary heart disease, clinical categories ranging from general population risk to personalized risk profiling are paralleled by the partition of risk predictors into the pathophysiologic categories of substrate-based risk and expression-based risk² (see Table 39-2B). Substrate-based risk refers to prediction of the evolution or identification of vascular or myocardial substrates that establish risk for SCD (i.e., atherogenesis, scar patterns, remodeling) and to quantification of these risks. It should not be perceived as limited to anatomic features because molecular variants may also provide risk substrates. In contrast, expression-based risk refers to the identification of mechanisms and pathways that contribute to the clinical manifestation of the risk established by the substrate. This category includes plaque transition and acute coronary syndromes (plaque disruption and thrombogenesis) and their potential for specific expression as an arrhythmic event in susceptible individuals. The arrhythmogenic

category of risk can also be viewed to include modifiers of molecular-based risk that drive individual expression.

Incidence and the Population Burden of Sudden Cardiac Death

The worldwide incidence of SCD is difficult to estimate because numbers vary as a function of the prevalence of coronary heart disease in different countries (see Chapter 1).³ The annual number of SCDs in the United States is derived from multiple sources, such as retrospective death certificate data, American Heart Association (AHA) statistical updates based on data from the National Center for Health Statistics,⁴ and national extrapolations from a large emergency rescue experience in one community⁵ and a community-wide multisource data set from another.⁶ Recently, data from large surveillance studies, such as the ROC (Resuscitation Outcomes Consortium), are contributing additional insight into the subtleties of data collection and interpretation.⁷

Statistical analyses from the same death certificate data sources have ranged from fewer than 250,000 SCDs annually when the etiologic definition is limited to coronary heart disease (International Classification of Diseases, ninth edition [ICD-9], classifications 410-414) to more than 460,000 SCDs per year when all causes are included.^{2-4,8} Extrapolations from the two community-based sources set nationwide figures at fewer than 200,000 SCDs per year.^{5,6} Because these broad ranges and the reported regional differences in incidence and outcomes of cardiac arrest⁹ suggest that an accurate number can be found only by performing carefully designed prospective epidemiologic surveillance studies, the most widely cited estimates remain in the range of 300,000 to 350,000 SCDs annually,¹⁰ as suggested in the 2012 AHA statistical update.⁴ These figures suggest an overall incidence of between one and two deaths per 1000 persons in the general population.

TABLE 39-2 Pathophysiologic Epidemiology and Power Cascade for Indicators of Risk for Sudden Cardiac Death

A. POWER CASCADE FOR RISK PREDICTION			
Strategy	Examples	Measures	Power
Conventional risk factors	Framingham risk index	Prediction of evolution of disease	High for the population Low for the individual
Anatomic disease screening	Calcium scoring and CT angiography	Identification of abnormal coronary arteries	High for anatomic identification Low for individual event prediction
Clinical risk profiling	Ejection fraction, stress testing, imaging techniques	Extent of disease	High for small, high-risk subgroups Low for large, low-risk subgroups
Transient risk predictors	Inflammatory markers	Prediction of unstable plaques	Uncertain feasibility
Personalized risk predictors	Familial/genetic profiles	Individual SCD expression	Uncertain clinical applicability; in evolution
B. PATHOPHYSIOLOGIC EPIDEMIOLOGY			
Substrate-based risk	Coronary heart disease State of epicardial and intramyocardial vessels Myocardial infarction Myopathy, infiltration, inflammation, valvulopathy Hypertrophy		
Expression-based risk	Left ventricular dysfunction and heart failure Metabolic abnormalities Autonomic fluctuations		
Mechanism-based causes	Ventricular fibrillation/pulseless ventricular tachycardia Pulseless electrical activity Asystole		

The temporal definition of sudden death strongly influences epidemiologic data. Retrospective death certificate studies have demonstrated that a temporal definition of sudden death of less than 2 hours after the onset of symptoms results in 12% to 15% of all natural deaths being defined as “sudden” and almost 90% of all natural sudden deaths having cardiac causes. In contrast, application of a 24-hour definition of sudden death increases the fraction of all natural deaths falling into the sudden category to more than 30% but reduces the proportion of all sudden natural deaths resulting from cardiac causes to 75%.

Prospective studies have demonstrated that approximately 50% of all deaths caused by coronary heart disease are sudden and unexpected and occur shortly (instantaneous to 1 hour) after the onset of symptoms. Because coronary heart disease is the dominant cause of both sudden and nonsudden cardiac deaths in the United States, the fraction of total cardiac deaths that are sudden is similar to the fraction of deaths from coronary heart disease that are sudden, although there does appear to be geographic variation in the fraction of coronary deaths that are sudden.^{8,9} It is also of interest that the age-adjusted decline in mortality from coronary heart disease in the United States during the past half-century has not changed the fraction of coronary deaths that are sudden and unexpected,^{11,12} even though there may be a decline in out-of-hospital deaths relative to emergency department deaths. Furthermore, the decreasing age-adjusted mortality does not imply a decrease in absolute numbers of cardiac or sudden deaths because of the growth and aging of the U.S. population and the increasing prevalence of chronic heart disease.⁸ There is uncertainty about whether the cumulative SCD burden is tracking the age-adjusted decrease in cardiac deaths that has been evolving during the past 40 to 50 years. The figures cited above suggest that SCD numbers have not decreased, although some studies suggest that it has.¹³

Population Pools, Risk Gradients, and Time Dependence of Risk

Three factors are of primary importance for identification of populations at risk and consideration of strategies for prevention of SCD: (1) the absolute numbers and event rates (incidence) among population subgroups (Fig. 39-2A), (2) the clinical subgroups in which SCDs occur (Fig. 39-2B), and (3) the time dependence of risk (Fig. 39-3).

Population and Subgroup Risk Versus Individual Risk Assessment

When the more than 300,000 adult SCDs that occur annually in the United States are viewed as a global figure for an unselected adult population 35 years and older, the overall incidence is calculated to be in the range of 0.1% to 0.2% per year (1 to 2/1000 population; see Fig. 39-2A). This general population includes the large proportion of SCDs that occur as a first clinical manifestation, as well as SCDs that can be predicted with greater accuracy in higher risk subgroups (see Fig. 39-2B). Any intervention designed for the general population must therefore be applied to the 999 per 1000 who do not have an event to reach and possibly influence the 1 per 1000 who does, in contrast to the much smaller subsets that can be profiled at higher risk. Figure 39-2A highlights this problem by expressing the incidence (percent per year) of SCD among various subgroups and comparing the incidence figures with the total number of events that occur annually in each subgroup. Thus, despite the large absolute number at risk in the general population and the impact of proven interventions on populations, the practical ability of applying the principles of population risk to targeted individual patients is challenging. The cost and risk-to-benefit uncertainties limit the nature of such broad-based interventions and demand a higher resolution of risk identification. Two fundamental approaches for attacking this challenge can be followed: a general population strategy targeting prevention of acquired risk factors such as obesity (primordial prevention) and primary prevention by control of manifest risk factors¹⁴ and a more focused individual risk strategy based on identification and intervention in small subsets of the general population with a high density of risk (Fig. 39-4).

On moving from the total adult population to a subgroup at higher risk because of the presence of selected coronary risk factors, there may be a 10-fold or greater increase in the annual incidence of events, with the magnitude being dependent on the number and types of risk factors operating in specific subgroups. The size of the denominator pool, however, remains very large, and implementation of interventions remains problematic, even at this heightened level of risk. Higher resolution is desirable and can be achieved by identification of more specific subgroups. However, the corresponding absolute

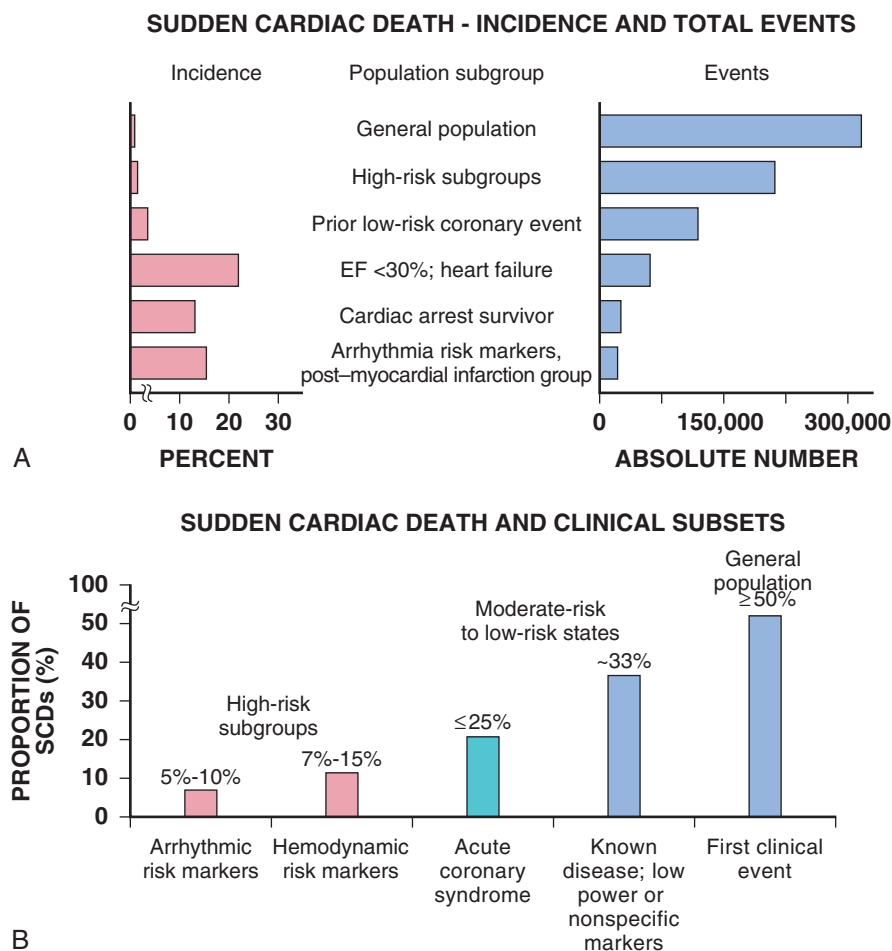

FIGURE 39-2 Impact of population subgroups and time from events on the clinical epidemiology of SCD. **A**, Estimates of incidence (percent per year) and the total number of events per year for the general adult population in the United States and for increasingly high-risk subgroups. The overall adult population has an estimated incidence of sudden death of 0.1% to 0.2% per year, which accounts for a total of more than 300,000 events per year. With the identification of increasingly powerful risk factors, the incidence increases progressively, but this is accompanied by a progressive decrease in the total number of events represented by each group. The inverse relationship between incidence and the total number of events is due to the progressively smaller denominator pool in the highest subgroup categories. In contrast to earlier iterations of this incidence profile, the magnitude of risk in the heart failure category exceeds that in the high-risk post-myocardial infarction and post-primary cardiac arrest groups. Successful interventions in larger population subgroups require identification of specific markers to increase the ability to identify specific patients who are at particularly high risk for a future event. (Note: The horizontal axis for the incidence figures is not linear and should be interpreted accordingly.) **B**, Distribution of the clinical status of victims at the time of SCD. Approximately 50% of all cardiac arrests caused by coronary heart disease occur as the first clinically manifested event, and up to an additional 30% occur in the clinical setting of known disease in the absence of strong risk predictors. Less than 25% of victims have high-risk markers based on arrhythmic or hemodynamic parameters. EF = ejection fraction. (**A**, Modified from Myerburg RJ, Castellanos A: Sudden cardiac death: Structure, function, and time-dependence of risk. *Circulation* 85[Suppl 1]:12, 1992; **B**, modified from Myerburg RJ: Sudden cardiac death: Exploring the limits of our knowledge. *J Cardiovasc Electrophysiol* 12:369, 2001.)

number of deaths becomes progressively smaller as the subgroups become more focused (see Fig. 39-2A), thus limiting the potential benefit of interventions to a much smaller fraction of the total number of patients at risk. Up to half of all SCDs attributable to coronary heart disease are first clinical events,² and another 20% to 30% occur in subgroups of patients with known coronary heart disease who are profiled to be at relatively low risk for SCD on the basis of current clinically available markers (see Fig. 39-2B). The principle of a high proportion of SCDs occurring as first events or in previously asymptomatic individuals applies to the less common causes as well.¹⁵

Biologic and Clinical Time-Dependent Risk

Temporal elements in risk for SCD have been analyzed in the context of both biologic and clinical chronology. In the former, epidemiologic analyses of risk for SCD in populations have identified three patterns: diurnal, weekly, and seasonal. General patterns of

heightened risk during the morning hours, on Mondays, and during the winter months have been described.¹⁶ An exception to the diurnal risk pattern is SCD in sleep apnea, in which the risk tends to be nocturnal.¹⁷

Ambient temperature is an environmental factor associated with risk for SCD. Both excessive cold¹⁸ and excessive heat¹⁹ have been linked to risk for cardiac arrest, although the studies did not determine whether temperature extremes are associated with ventricular tachyarrhythmias versus other mechanisms of cardiac arrest. Another environmental variable, transient ambient air pollution conditions, has been correlated with an increased incidence of ventricular arrhythmias stored in implantable cardioverter-defibrillator (ICD) memories,²⁰ but the question of whether these are cardiac arrest equivalents is uncertain.

In the longer-term clinical paradigm, risk for SCD is not linear as a function of time after changes in cardiovascular status.^{10,11,21} Survival curves after major cardiovascular events, which identify risk for both sudden and total cardiac death, usually demonstrate that the most rapid rate of attrition occurs during the first 6 to 18 months after an index event (see Fig. 39-3). Thus there is a time dependence of risk that focuses the potential opportunity for maximum efficacy of an intervention during the early period after a conditioning event. Curves that have these characteristics have been generated from among survivors of out-of-hospital cardiac arrest, new onset of heart failure, and unstable angina and from patients with recent myocardial infarction and low ejection fractions or heart failure. For the latter, however, early non-arrhythmic deaths also contribute a large proportion of the fatal events. Even though the rate of attrition decreases after the early spike in mortality, a secondary delayed increase in risk occurs in post-myocardial infarction patients 2 to 5 years after an index event, probably related to ventricular remodeling and heart failure.

Age, Race, Sex, and Heredity

Age. The incidence of sudden death has two peak ages: within the first year of life (including sudden infant death syndrome [SIDS]; see Chapter 62) and between 45 and 75 years of age. Among the general populations of infants younger than 1 year and middle-aged or older adults, the incidence is surprisingly similar.²² In adults older than 35 years, the incidence of SCD is 1 per 1000 persons per year (Fig. 39-5A), with an age-related increase in risk over time as the prevalence of coronary heart disease increases as a function of advancing age.¹⁰ The incidence in infants is 73 per 100,000 person-years, and the incidence in adolescents and adults younger than 30 years is approximately 6 per 100,000 person-years,^{22,23} or 1% of the risk in middle-aged and older adults (Fig. 39-5A). In contrast to incidence, however, the proportion of deaths caused by coronary heart diseases that are sudden and unexpected decreases with advancing age. In the 20- to 39-year age group, approximately 75% of the deaths attributable to coronary heart disease in men are sudden and unexpected, with the proportion falling to approximately 60% in the 45- to 54-year age group and hovering close to 50% thereafter. Age also influences the proportion of any cardiovascular cause among all causes of natural sudden death in that the proportion of coronary deaths and of all cardiac causes of death that are sudden is highest in the younger age groups whereas the fraction of total sudden natural deaths that result from any cardiovascular cause is higher in the older age groups. At the other end

FIGURE 39-3 Time-dependent risk for SCD after myocardial infarction (MI). The natural history of a population of patients with major risk factors or known cardiovascular disease but at low risk because of freedom from major cardiovascular events (*top curve*) is compared with that of patients who have survived a myocardial infarction (*bottom curve*). Risk for SCD is accelerated during the initial 6 to 18 months after the major cardiovascular event and then plateaus, followed by a secondary acceleration during the next 2 to 3 years, probably because of the consequences of remodeling. (Modified from Myerburg RJ, Kessler KM, Castellanos A: Sudden cardiac death: Structure, function, and time-dependence of risk. *Circulation* 85[Suppl I]:12, 1992.)

FIGURE 39-4 Stratification of risk as a continuum across the population. The mean risk in the general population is demonstrated as a continuum across four decades. The mean risk of approximately 0.1% to 0.2% per year is bracketed by extremes of higher and lower risk strata, with the larger absolute numbers accumulated in the lower risk strata. Potentially identifiable subgroups with varying risk densities populate each range of risk. The ability to identify high-risk density subgroups within the general population would contribute to better individual risk prediction. (Modified from Myerburg RJ, Junttila MJ. Sudden cardiac death caused by coronary heart disease. *Circulation* 125:1043, 2012.)

of the age range, only 19% of sudden natural deaths in children between 1 and 13 years of age have cardiac causes; the proportion increases to 30% in the 14- to 21-year age group.

In the transition age range between adolescence and young adulthood (to the age of 25 years) and in the middle and older ages (beginning at 35 years of age), coronary heart disease emerges to its position as the dominant cause of SCD. However, rare disorders, such as hypertrophic cardiomyopathy, Brugada syndrome, long-QT syndrome, and right ventricular dysplasia, are significant contributors to the distribution of causes of SCD in this age group. In one study, myocardial fibrosis of unknown etiology was a significant cause in this age group.²⁴

Race. A number of studies comparing racial differences in the relative risk for SCD in whites and blacks with coronary heart disease in the United States had yielded conflicting and inconclusive data. However, the most recent studies demonstrate a higher risk for cardiac arrest and SCD in blacks than in whites (see Fig. 39-5B and Chapter 2).²⁵ SCD rates in Hispanic populations were lower. These differences were observed across all age groups.

Sex. SCD syndrome has a large preponderance in men relative to women during the young adult and early middle-age years because of the protection that women enjoy from coronary atherosclerosis before menopause (see Fig. 39-5B). Various population studies have demonstrated a fourfold to sevenfold greater incidence of SCD in men than in women before 65 years of age, at which point the difference decreases to 2:1 or less, and continues to decrease with advancing age. As risk for coronary events increases in postmenopausal women, risk for SCD increases proportionately, with similar rates in men and women. Even though the overall risk for SCD is much lower in younger women, coronary artery disease is the most common cause of SCD in women older than 40 years, and the classic coronary risk factors, including cigarette smoking, diabetes, use of oral contraceptives, and hyperlipidemia, all influence risk in women (see Chapter 77).²⁶ Data from the Nurses' Health Study suggest that a healthy lifestyle, defined as no cigarette smoking, a low body mass index, regular exercise, and a healthy diet, reduces the risk for SCD in women by as much as 46% to more than 90%, depending on the number of low-risk markers present.²⁷ Women are 50% less likely to have severe left ventricular dysfunction and 66% less likely to have known coronary heart disease before SCD²⁸ and are therefore less likely to be profiled as high risk and more likely to have SCD as a first cardiac event.

Heredity. Familial patterns of risk for SCD, which result from known or suspected genetic variations, are emerging as important factors for risk profiling. This concept is generally applicable in regard to both disease development and SCD expression in the common acquired disorders and in a specific sense to inherited arrhythmogenic conditions associated with SCD. The various genetic associations can be separated into four categories (Table 39-3): inherited uncommon primary arrhythmic syndromes (e.g., long-QT syndromes, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia or fibrillation), inherited uncommon structural diseases associated with risk for SCD (e.g., hypertrophic cardiomyopathy, right ventricular dysplasia), "acquired" or induced risk for arrhythmias (e.g., drug-induced long QT interval or proarrhythmia, electrolyte disturbances), and common acquired diseases associated with risk for SCD (e.g., coronary heart disease, nonischemic cardiomyopathies) (see Chapters 32 and 33). Genetic variants mapped to loci on many chromosomes are being defined as the molecular bases for these entities and associations.

The multiple specific mutations at gene loci encoding ion channel proteins associated with the various inherited arrhythmia syndromes (see Chapter 32) represent a major advance in the understanding of a genetic and pathophysiologic basis for these causes of sudden death. In addition, the role of modifier genes and mutation specificity in the severity of clinical phenotypes in long-QT interval syndromes^{29,30} and structural diseases such as hypertrophic cardiomyopathy³¹ is of increasing interest. These observations may provide screening tools for individuals at risk, as well as the potential to devise specific therapeutic strategies. In addition, gene loci identified by genome-wide association studies may also serve as candidates for investigation of the role of low-penetrance mutations or polymorphisms in SCD caused by more common conditions, such as coronary heart disease.³² At this time it appears that the hope for common variants linked to common syndromes such as SCD will be superseded by multiple rare variant associations.

To the extent that SCD is an expression of underlying coronary heart disease, hereditary factors that contribute to risk for coronary heart disease operate nonspecifically for the SCD syndrome. However, studies have identified mutations and relevant polymorphisms along multiple steps of the cascade, from atherogenesis to plaque destabilization, thrombosis, and arrhythmogenesis, each of which is associated with increased risk for a coronary event (Fig. 39-6).^{33,34} Integration of these individual markers may provide more powerful individual risk prediction in the future. In addition, several studies have suggested that SCD as the initial expression of coronary heart disease demonstrates familial clustering,³⁵⁻³⁸ including general population surveillance studies, family histories of cardiac arrest survivors in the community, studies of ventricular fibrillation (VF) during acute myocardial infarction, and postmortem evaluation of SCD cases (Table 39-4).

Risk Factors for Sudden Cardiac Death

General Profile of Risk for Sudden Cardiac Death

(see Chapters 32 and 33)

Risk profiling for coronary artery disease, by means of the conventional risk factors for coronary atherogenesis, is useful to identify levels of population risk and individual risk but cannot be used to distinguish individual patients at risk for SCD from those at risk for other manifestations of coronary heart disease (see Chapters 49 to 54). Multivariate analyses of selected risk factors (e.g., age, diabetes mellitus, systolic blood pressure, heart rate, electrocardiographic abnormalities, vital capacity, relative weight, cigarette consumption, and serum cholesterol level) have determined that approximately

50% of all SCDs occur in the 10% of the population in the highest risk decile on the basis of multiple risk factors (Fig. 39-7). Thus the cumulative risk derived from multiple risk factors exceeds the simple arithmetic sum of the individual risks. Comparison of risk factors in victims of SCD with those in people in whom any manifestation of coronary artery disease develops does not provide useful patterns, by either univariate or multivariate analysis, to distinguish victims of SCD from the overall pool. However, a history of diabetes mellitus and a tendency to longer QTc intervals on random electrocardiograms are suggested as potential markers of interest for prediction of SCD.³⁹ Although angiographic and hemodynamic patterns discriminate SCD risk from non-SCD risk only under limited conditions, familial clustering of SCD as a specific manifestation of the disease may

lead to the identification of specific genetic abnormalities that predispose to SCD.³⁶⁻³⁸

Hypertension is a clearly established risk factor for coronary heart disease and also emerges as a highly significant risk factor in the incidence of SCD (see Chapters 43 and 44). However, there is no influence of increasing systolic blood pressure levels on the ratio of sudden deaths to total coronary heart disease deaths. No relationship has been observed between cholesterol concentration and the proportion of coronary deaths that were sudden. Neither the electrocardiographic pattern of left ventricular hypertrophy nor nonspecific ST-T wave abnormalities influence the proportion of total coronary deaths that are sudden and unexpected; only intraventricular conduction abnormalities are suggestive of a disproportionate number of SCDs, an old observation reinforced by data from some device trials that suggest the importance of QRS duration as a risk marker. Low vital capacity also suggests a disproportionate risk for sudden versus total coronary deaths. This is of interest because such a relationship was particularly striking in the Framingham Study in analysis of data from women who had died suddenly.

The conventional risk factors used in early studies of SCD are risk factors for the evolution of coronary artery disease. The rationale is based on two facts: (1) coronary disease is the structural basis for 80% of SCDs in the United States, and (2) coronary risk factors are easy to identify because they tend to be present continuously over time (see Fig. 39-6). However, risk factors specific for fatal arrhythmias are dynamic pathophysiologic events and occur transiently.⁴⁰ Transient pathophysiologic events are being modeled epidemiologically in an attempt to express and use them as clinical risk factors for both profiling and intervention.¹ Nonetheless, data suggest that longitudinal and transient risk predictors may have their power blunted by clinical interventions, such as percutaneous coronary intervention during acute coronary syndromes and post-myocardial infarction beta blocker therapy.^{41,42}

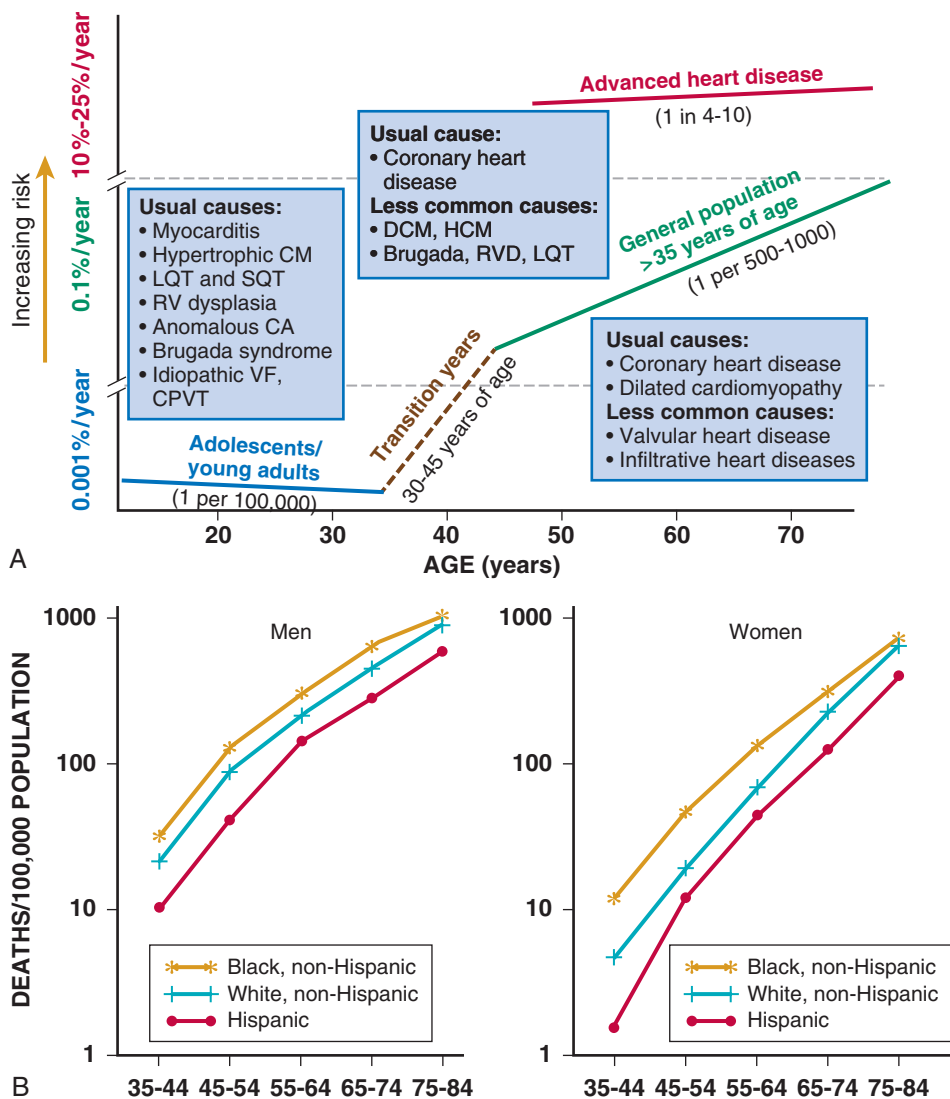

FIGURE 39-5 Age-, sex-, and race-specific risks for SCD. **A**, Age-related and disease-specific risk for SCD. For the general population 35 years and older, the risk for SCD is 0.1% to 0.2% per year (1/500 to 1000 population), with a wide spread in subgroup risk based on the number and power of individual risk factors. Causes are dominated by coronary heart disease and, to a lesser extent, nonischemic cardiomyopathy in this age range. The risk for SCD increases dramatically beyond the age of 35 years and continues to increase past the age of 70 years. In patients older than 30 years with advanced structural heart disease and markers of high risk for cardiac arrest, the event rate may exceed 25% per year, and the age-related risk is attenuated. In adolescents and adults younger than 30 years, the overall risk for SCD is 1 per 100,000 population or 0.001% per year, with a variety of causes such as inherited structural and electrical disorders, developmental defects, and myocarditis dominating. In adolescents and young adults at risk for SCD from specific identified causes, it is difficult to ascertain the risk in individual patients because of variable expression of the disease state (see text for details). In the transition range from 30 to 45 years of age, the relative frequency of the uncommon disease yields to the dominance of coronary heart disease and nonischemic cardiomyopathy, but both groups of potential causes must be entertained because many of the rare disorders are expressed in that age range. **B**, SCD risk as a function of age, sex, and race (white, black, and Hispanic). CA = cardiac arrest; CM = cardiomyopathy; CPVT = catecholaminergic polymorphic VT; DCM = dilated CM; HCM = hypertrophic CM; LQT = long QT; RV = right ventricular; RVD = RV dysplasia; SQT = short QT; VF = ventricular fibrillation. (B, Data modified from Gillum RF: Sudden cardiac death in Hispanic Americans and African Americans. *Am J Public Health* 87:1461, 1997.)

TABLE 39-3 Genetic Contributors to Risk for Sudden Cardiac Death

Genetically Based Primary Arrhythmia Disorders
Congenital long-QT interval syndrome, short-QT syndrome Brugada syndrome Catecholaminergic polymorphic ("idiopathic") ventricular tachycardia/ ventricular fibrillation
Inherited Structural Disorders with Risk for Arrhythmic SCD
Hypertrophic cardiomyopathy Right ventricular dysplasia/cardiomyopathy
Genetic Predisposition to Induced Arrhythmias and SCD
Drug-induced "acquired" long-QT interval syndrome (drugs, electrolytes) Electrolyte and metabolic arrhythmogenic effects
Genetic Modulation of Complex Acquired Diseases
Coronary artery disease, acute coronary syndromes Congestive heart failure, dilated cardiomyopathies

Identification of specific clinical markers of risk for SCD as a specific expression of both coronary heart disease and other cardiovascular disorders has been a goal for many years.^{10,11} Left ventricular ejection fraction has been the most popular of such markers for clinical trials and patient profiling. However, its sensitivity limitations and inability to identify the large subgroup in which SCD is the first expression of heart disease have encouraged investigators to seek additional markers. For example, exercise data from a large cohort of men observed for years after a stress test demonstrated that a profile of higher resting heart rates, smaller increments in rate during exercise, and lower decrement in heart rate during the first minute after exercise predicted higher risk for SCD during follow-up.⁴³ In addition, a number of electrocardiographic indicators (such as micro-volt T wave alternans and indices of QT duration and dispersion), genetic profiles, and other indices of the extent of disease are also predictive (see Chapters 35 and 37).

Functional Capacity and Sudden Death

The Framingham Study demonstrated a striking relationship between functional classification and death during a 2-year follow-up period. However, the proportion of deaths that were sudden did not vary with

the functional classification, with a range of 50% to 57% in all groups, including those free of clinical heart disease and those in functional class IV. Other studies have also suggested that patients with heart failure and better functional capacity are at lower risk for dying, as expected, but that a higher proportion of such deaths are sudden.⁴⁴

Lifestyle and Psychosocial Factors

(see Chapter 86)

A strong association has been found between cigarette smoking and all manifestations of coronary heart disease. The Framingham Study demonstrated that cigarette smokers have a twofold to threefold increase in risk for sudden death in each decade of life at entry between 30 and 59 years and that this is one of the few risk factors in which the proportion of deaths attributable to coronary heart disease that are sudden increases in association with the risk factor. The excess risk for SCD in current smokers with coronary heart disease was not observed in former smokers, whose risk was similar to that of those who never smoked.⁴⁵ In addition, in a study of 310 survivors of out-of-hospital cardiac arrest, the recurrent cardiac arrest rate was 27% at 3 years of follow-up in those who continued to smoke versus 19% in those who stopped. Conversely, light to moderate alcohol consumption was associated with a reduced risk for SCD in male physicians.⁴⁶ Obesity is a second factor that appears to influence the

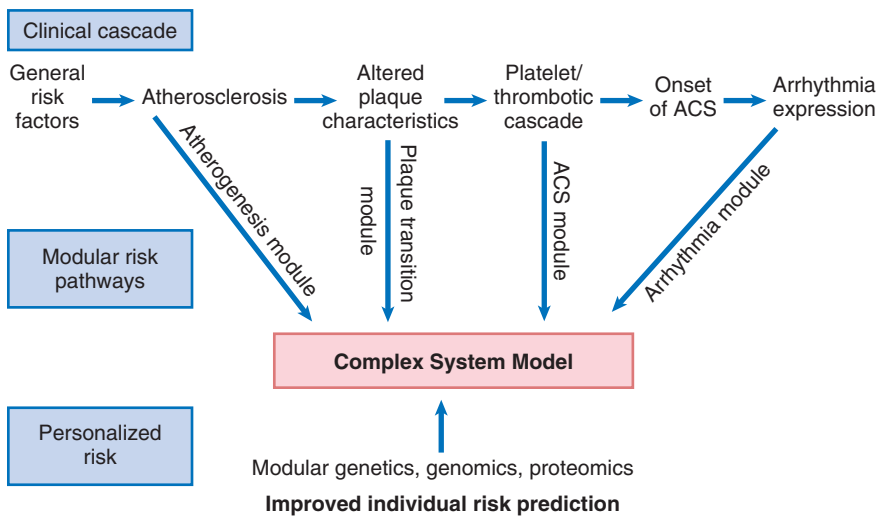

FIGURE 39-6 Coronary atherosclerosis heart disease cascade and genetic imprints on the progression to SCD. The cascade from conventional risk factors for coronary atherosclerosis to arrhythmogenesis in SCD related to coronary heart disease includes initiation and development, progression to an active state, initiation of acute coronary syndromes (ACSs), and finally, progression to the specific expression of life-threatening arrhythmias. Multiple factors enter at each level, including specific risk based on the genetic profiles of individual patients. Individual risk based on genetic profiles has been identified for atherogenesis, plaque evolution, the thrombotic cascade, and arrhythmia expression. Stepwise integration of these characteristics for individuals through genetics, genomics, proteomics, and biologic system analyses offers the hope of a field of molecular epidemiology that may lead to higher single-patient probabilities for individual SCD risk prediction. See text for details. (Modified from Myerburg RJ, Junttila MJ: Sudden cardiac death caused by coronary heart disease. *Circulation* 125:1043, 2012.)

TABLE 39-4 Family History of and Risk for Primary Sudden Cardiac Death

STUDY SITE	COHORT	CONTROLS	FAMILY HISTORY MEASURE	OUTCOME
Seattle ³⁵ 1988-1994	EMS SCA subjects	Population matched	Hx of MI or PCA in 1° relatives	2.85 vs. 1.96/1000/yr RR = 1.57 (95% CI, 1.27-1.95)
Paris ³⁶ 1967-1994	Population surveillance	Retrospective analysis	Hx of PCA in 1° relatives	18.6% vs. 9.9% OR = 1.80 (95% CI, 1.11-2.88)
Netherlands ³⁷ 2001-2005	STEMI with VF	STEMI without VF	Hx of SCD in 1° relatives	43.1% vs 25.1% OR = 2.72 (95% CI, 1.84-4.03)
Finland ³⁸ 2000-2003	SCD with AMI AMI survivors	Population controls	SCD or AMI in 1° relatives without ASHD	SCD = 5.2%; AMI = 3.3% OR for SCD/AMI = 1.6 (95% CI, 1.2-2.2; P = 0.01)
				SCD = 5.2%; Controls = 2.3% OR for SCD/controls = 2.2 (95% CI, 1.6-3.0; P = 0.001)

AMI = acute myocardial infarction; ASHD = arteriosclerotic heart disease; CI = confidence interval; EMS = emergency medical service; Hx = history; MI = myocardial infarction; OR = odds ratio; PCA = primary cardiac arrest; RR = relative risk; STEMI = ST-segment elevation myocardial infarction.

proportion of coronary deaths that occur suddenly. With increasing relative weight, the percentage of coronary heart disease deaths that were sudden in the Framingham Study increased linearly from a low of 39% to a high of 70%. Total coronary heart disease deaths increased with increasing relative weight as well.

Associations between levels of physical activity and SCD have been studied with variable results. Epidemiologic observations have suggested a relationship between low levels of physical activity and increased risk for death from coronary heart disease. The Framingham Study, however, showed an insignificant relationship between low levels of physical activity and the incidence of sudden death but a high proportion of sudden to total cardiac deaths with higher levels of physical activity. An association between acute physical exertion and the onset of myocardial infarction has been suggested, particularly in individuals who are habitually physically inactive. A subsequent case-crossover cohort study confirmed this observation for SCD by demonstrating a 17-fold relative increase in SCD associated with vigorous exercise as opposed to lower level activity or inactive states.⁴⁷ However, the absolute risk for events was very low (one event per 1.5 million exercise sessions). Habitual vigorous exercise markedly attenuated risk. In contrast, SCD has a higher incidence in young athletes than in young nonathletic individuals in the same age range (see Chapter 79). Information about physical activity relationships in various clinical settings, such as overt and silent disease states, is still lacking.

The magnitude of recent life changes in the realms of health, work, home and family, and personal and social factors has been related to myocardial infarction and SCD. There is an association with significant elevations in life change scores during the 6 months before a coronary event, and the association is particularly striking in victims of SCD. In women, those who die suddenly were less often married, had fewer children, and had greater educational discrepancies with their spouses than did age-related control subjects living in the same neighborhood as the victims of sudden death. A history of psychiatric treatment, including phobic anxieties,⁴⁸ cigarette smoking, and greater quantities of alcohol consumption than in control subjects also characterized the sudden death group. After controlling for other major prognostic factors, the risk for sudden and total deaths and other coronary events is affected by social and economic stress. Alteration of modifiable lifestyle factors has been proposed as a strategy to reduce the risk for SCD in patients with coronary heart disease, although studies of pharmacologic and psychotherapeutic treatment of depression after myocardial infarction failed to demonstrate an effect on event rates, even though the symptoms of depressive states improved.⁴⁹ Behavioral changes (e.g., inactivity) secondary to depression appeared to relate more closely to event rates than did depression itself. Acute psychosocial stressors have been associated with a higher risk for cardiovascular events, including SCD.^{50,51} The risk appears to cluster around the time of the stress and seems to occur in victims with preexisting risk, with the stressor simply advancing the time of an impending event. The possibility of physical stress-induced coronary plaque disruption has also been suggested.

Left Ventricular Ejection Fraction in Chronic Ischemic Heart Disease

A marked reduction in the left ventricular ejection fraction is the most powerful of the known predictors of SCD in patients with chronic ischemic heart disease, as well as in those at risk for SCD from other causes (see later). Increased risk, independent of other risk factors, is measurable with ejection fractions higher than 40%, but the greatest rate of change in risk occurs at levels between 30% and 40%. An ejection fraction of 30% or lower is the single most powerful independent predictor of SCD but has low sensitivity and specificity.⁵² Nonetheless, relying on a low ejection fraction as the sole major predictor limits the predictive power because of the large number of SCDs that occur at low incidence rates among the very large subset of patients with normal or moderately reduced ejection fractions and unrecognized disease.⁵³ There are emerging implications that left ventricular volume may be a better predictor of cardiac events than ejection fraction alone.^{54,55}

Ventricular Arrhythmias in Chronic Ischemic Heart Disease

Most forms of ambient ventricular ectopic activity (premature ventricular complexes [PVCs] and short runs of nonsustained ventricular tachycardia [VT]) have a benign prognosis in the absence of structural heart disease (see Chapters 37 and 54). An exception is the polymorphic forms of nonsustained VT that occur in patients without structural heart disease but can have a molecular, functional, drug-related, or electrolyte-related basis for high-risk arrhythmias. When they are present in subjects in the coronary-prone age groups, however, PVCs select a subgroup with a higher probability of coronary artery disease and SCD. Exercise-induced PVCs and short runs of nonsustained VT indicate some level of risk for SCD, even in the absence of recognizable structural heart disease. However, the data available to support this hypothesis are conflicting, with the possible exception of polymorphic runs of nonsustained VT. Additional data suggest that PVCs and nonsustained VT during both the exercise and recovery phases of a stress test are predictive of increased risk.⁵⁶ Arrhythmias in the recovery phase, previously thought to be benign, appear to predict higher risk than do arrhythmias in the exercise phase, and there is a gradient of risk with increasing severity of arrhythmias.

The occurrence of PVCs in survivors of myocardial infarction, particularly if frequent and having complex forms such as repetitive PVCs, predicts an increased risk for SCD and total mortality during long-term follow-up. Data are conflicting on the role of measures of frequency and forms of ventricular ectopic activity as discriminators of risk, but most studies have cited a frequency cutoff of 10 PVCs per hour as a

threshold level for increased risk. Several investigators have emphasized that the most powerful predictors among the various forms of PVCs are runs of nonsustained VT, although this relationship is now questioned. Many of the reported studies have been based on a single ambulatory monitor sample recorded 1 week to several months after the onset of acute myocardial infarction, and the duration of the samples has ranged from 1 to 48 hours. Other studies have suggested that ambulatory ventricular arrhythmias in patients with heart failure do not specifically predict an increased risk for death.

The results of CAST (Cardiac Arrhythmia Suppression Trial; see Chapter 35), which was designed to test the hypothesis that suppression of PVCs by antiarrhythmic drugs alters the risk for SCD after myocardial infarction, were surprising for two reasons. First, the death rate in the randomized placebo group was lower than expected, and second, the death rate among patients in the encainide and flecainide arms exceeded control rates by more than threefold. Subgroup analysis has demonstrated increased risk for patients with nonsustained VT and an ejection fraction of 30% or

FIGURE 39-7 Risk for sudden death by decile of multivariate risk—the Framingham Study. Selected risk variables are shown. (Modified from Kannel WB, Shatzkin A: Sudden death: Lessons from subsets in population studies. *J Am Coll Cardiol* 5[Suppl 6]:141B, 1985. Reprinted by permission of the American College of Cardiology.)

less in the placebo group, but excess risk in the treated group was still observed. The excess death rates may be accounted for by the occurrence of ischemic events in the presence of drug. No adverse effect (other than short-term proarrhythmic risk at initiation of therapy) was observed with the other drug in the study (moricizine); nor did long-term benefit emerge with further study. The SWORD (Survival with Oral *d*-Sotalol) study, a comparison of *d*-sotalol with placebo in a post-myocardial infarction population with a low death rate, also demonstrated excess risk in the drug-treated group. Whether the conclusions from CAST, CAST II, and SWORD extend beyond the drugs studied or to other diseases remains to be learned.

Left ventricular dysfunction is the major modulator of risk implied by chronic PVCs after myocardial infarction. The risk for death predicted by post-myocardial infarction PVCs is enhanced by the presence of left ventricular dysfunction, which appears to exert its influence most strongly in the first 6 months after infarction. Delayed deterioration of left ventricular function, probably because of remodeling after myocardial infarction, may increase the risk further. Finally, some data suggest that the risk associated with postinfarction ventricular arrhythmias is higher in patients who have non-Q-wave infarctions than in those with transmural infarctions.

Emerging Markers of Risk for Sudden Cardiac Death

Additional risk markers with independent or added predictive power are being studied for risk profiling. Among these are techniques such as microvolt T wave alternans,⁵⁷ contrast-enhanced magnetic resonance imaging of the postinfarction border,⁵⁸ measures of QT variability,⁵⁹ derivatives of heart rate variability methods,^{60,61} ¹²⁴I-m-iodobenzylguanidine (MIBG) imaging,⁶² and studies of familial clustering of SCD as an expression of coronary heart disease³⁵⁻³⁸ and for the potential of genetic risk profiling.² With the possible exception of the predictive accuracy of a negative T wave alternans study,⁶³ these techniques are all in their infancy in terms of clinical application.

CAUSES OF SUDDEN CARDIAC DEATH

Coronary Artery Abnormalities

Disease of the coronary arteries and its consequences account for at least 80% of SCDs in Western countries, and the nonischemic cardiomyopathies are responsible for another 10% to 15%. Coronary artery disease is also the most common cause in many areas of the world in which the prevalence of atherosclerosis is lower. In regard to the latter, it is anticipated that as third-world countries improve access to health care for communicable disease in the earlier years of life, coronary atherosclerosis and its consequences will emerge as a larger problem.⁶⁴

Despite the established dominant relationship between coronary atherosclerosis and SCD, complete understanding of SCD requires recognition that less common and often rare coronary vascular disorders (Table 39-5) may be identifiable before death and have therapeutic implications. Many of these entities are relatively more common causes of SCD in adolescents and young adults, in whom the prevalence of coronary atherosclerosis is much lower (see Fig. 39-5A).

Atherosclerotic Coronary Artery Disease

The structural and functional abnormalities of the coronary vasculature as a result of coronary atherosclerosis interact with the electrophysiologic alterations that result from the myocardial impact of an ischemic burden (see Chapters 51 to 55). The relationship between the vascular and myocardial components of this pathophysiologic model, as well as its modulation by hemodynamic, autonomic, genetic, and other influences, establishes multiple patterns of risk derived from the fundamental disease state² (Fig. 39-8). Risk is modulated by multiple factors that can be either transient or persistent, and transient modulations may interact with persistent changes. The myocardial component of this pathophysiologic model is not static over time, and the term *persistent* must be viewed with caution because of the gradual effects of remodeling after an initial ischemic

event and the effects of recurrent ischemic events. Cardiac arrest and SCD resulting from transient ischemia or acute myocardial infarction differ in physiology and prognosis from the risk for cardiac arrest implied by a previous myocardial infarction with or without subsequent ischemic cardiomyopathy. In general, the short-term risk for life-threatening events is associated more closely with acute ischemia or the acute phase of myocardial infarction, and longer term risk is associated more with transient ischemia, myocardial scarring, remodeling, ischemic cardiomyopathy, and heart failure.

Nonatherosclerotic Coronary Artery Abnormalities

Nonatherosclerotic coronary artery abnormalities include congenital lesions, coronary artery embolism, coronary arteritis, and mechanical abnormalities of the coronary arteries. Among the congenital lesions, anomalous origin of a left coronary artery from the pulmonary artery (see Chapters 62 and 79) is relatively common and associated with a high death rate in infancy and early childhood without surgical treatment. The early risk for SCD is not excessively high, but patients who survive to adulthood without surgical intervention are at risk for SCD. Other forms of coronary arteriovenous fistulas are much less frequent and associated with a low incidence of SCD.

Anomalous Origin of Coronary Arteries from the Wrong Sinus of Valsalva. These anatomic variants are associated with an increased risk for SCD, particularly during exercise. When the anomalous artery passes between the aortic and the pulmonary artery root, the takeoff angle of the anomalous ostium creates a slitlike opening of the vessel that reduces the effective cross-sectional area for blood flow. Congenitally hypoplastic, stenotic, or atretic left coronary arteries are uncommon abnormalities associated with a risk for myocardial infarction in the young, but not for SCD.

Embolism to the Coronary Arteries. Coronary artery emboli occur most commonly in aortic valve endocarditis and from thrombotic material on diseased or prosthetic aortic or mitral valves. Emboli can also originate from left ventricular mural thrombi or as a consequence of surgery or cardiac catheterization. Symptoms and signs of myocardial ischemia or infarction are the most common manifestations. In each of these categories, SCD is a risk resulting from the electrophysiologic consequences of embolic ischemia.

Coronary Arteritis. Mucocutaneous lymph node syndrome (Kawasaki disease; see Chapter 84) carries a risk for SCD in association with coronary arteritis. Polyarteritis nodosa and related vasculitis syndromes can cause SCD, presumably because of coronary arteritis, as can coronary ostial stenosis in syphilitic aortitis. The latter has become a rare manifestation of syphilis.

Mechanical Obstruction of Coronary Arteries. Several types of mechanical abnormalities are listed among the causes of SCD. Coronary artery dissection, with or without dissection of the aorta, occurs in Marfan syndrome (see Chapter 62) and has also been reported after trauma and in the peripartum period of pregnancy. Among the rare mechanical causes of SCD is prolapse of myxomatous polyps from the aortic valve into the coronary ostia, as well as dissection or rupture of a sinus of Valsalva aneurysm with involvement of the coronary ostia and proximal coronary arteries. Finally, deep myocardial bridges over coronary arteries (see Chapter 79) have been reported in association with SCD occurring during strenuous exercise, possibly caused by dynamic mechanical obstruction. Scattered fibrosis in the distribution of the affected vessel is commonly seen at postmortem examination and suggests a chronic or intermittent ischemic burden over time. Deep bridging seems to be more common in association with hypertrophic cardiomyopathy. However, the more common superficial bridges in the absence of other disorders are of less concern, and SCD associated with this anatomy is uncommon.

Coronary artery spasm. Coronary vasospasm may cause serious arrhythmias and SCD (see Chapter 51). It is usually associated with some degree of concomitant coronary atherosclerotic disease. Painless myocardial ischemia, associated with either spasm or fixed lesions, is recognized as a mechanism of previously unexplained sudden death. It has been suggested that based on absence of markers of risk for a high rate of recurrence, patients with documented life-threatening arrhythmias associated with vasospastic angina receive both medical therapy and ICDs.⁶⁵ Different patterns of silent ischemia (e.g., totally asymptomatic, post-myocardial infarction, and mixed silent anginal patterns) may have different prognostic implications. In post-myocardial infarction patients, silent ischemia has been correlated with an increased risk for SCD.⁶⁶

Ventricular Hypertrophy and Hypertrophic Cardiomyopathy

Left ventricular hypertrophy is an independent risk factor for SCD, is associated with many causes of SCD, and may be a physiologic contributor to mechanisms of potentially lethal arrhythmias. Underlying states resulting in left ventricular hypertrophy include hypertensive heart disease with or without atherosclerosis, valvular heart disease, obstructive and nonobstructive hypertrophic cardiomyopathy (see Chapters 66 and 79), primary pulmonary hypertension with right ventricular hypertrophy, and advanced right ventricular overload secondary to congenital heart disease. Each of these conditions is associated with risk for SCD, and it has been suggested that patients with severely hypertrophic ventricles are particularly susceptible to arrhythmic death.

Risk for SCD in patients with obstructive and nonobstructive hypertrophic cardiomyopathy was identified in the early clinical and hemodynamic descriptions of this entity. In patients who have the obstructive form, up to 70% of all deaths are sudden. However, survivors of cardiac arrest in this group may have a better long-term outcome than might survivors with other causes, and reports have suggested that the risk for primary cardiac arrest and SCD in those with hypertrophic cardiomyopathy is lower than previously thought.

A substantial proportion of patients with obstructive and nonobstructive hypertrophic cardiomyopathy have a family history of affected relatives or premature SCDs of unknown cause. Genetic studies have confirmed autosomal dominant inheritance patterns, but with a great deal of allele and phenotypic heterogeneity. Most of the mutations are at loci that encode elements in the contractile protein complex, the most common being beta-myosin heavy chain and cardiac troponin T, which together account for more than half of identified abnormalities. In the beta-myosin heavy chain form, there is a relationship between the severity of left ventricular hypertrophy and risk for SCD; in the troponin T form, left ventricular hypertrophy may be less severe despite risk for SCD. The genetics of hypertrophic cardiomyopathy is characterized by a large number of private mutations with variable expression. Possible interaction with modifier genes, such as variations in ion channel genes, remains to be clarified.

Specific clinical markers have not been especially predictive of SCD in individual patients, although young age at onset, a strong family history of SCD, magnitude of the left ventricular mass, ventricular arrhythmias, and worsening symptoms (especially syncope) appear to indicate higher risk. Early studies suggested that a low resting outflow gradient, along with a substantial provokable gradient, identifies high risk for SCD, but recent data support the predictive power of a high resting gradient.⁶⁷ The mechanism of SCD in patients with hypertrophic cardiomyopathy was initially thought to involve outflow tract obstruction, possibly as a consequence of catecholamine stimulation, but later data have focused on lethal arrhythmias as the common mechanism of sudden death in this disease. Risk is also thought to be suggested by nonsustained VT on ambulatory recording, inducibility of potentially lethal arrhythmias during programmed electrical stimulation, or a fall in blood pressure during exercise. Rapid or polymorphic symptomatic nonsustained tachycardias, or both, have better predictive power.

The question of whether the pathogenesis of the arrhythmias represents an interaction between electrophysiologic and hemodynamic abnormalities or is a consequence of electrophysiologic derangement of hypertrophied muscle is unanswered. The observation that patients

FIGURE 39-8 Pathophysiology of ventricular tachyarrhythmias in coronary heart disease. The short- and long-term risks for the development of VT or VF and recurrent events are related to the presence of transient or persistent physiologic factors. VT/VF caused by transient ischemia (A) and the acute phase (24 to 48 hours) of myocardial infarction (B) are not predictive of recurrent events if the recurrent ischemia is preventable. In contrast, VT/VF associated with healed myocardial infarction, with or without acute transient ischemia (C), is associated with risk for recurrence. Longstanding ischemic cardiomyopathy (D), especially when accompanied by heart failure, establishes a substrate associated with risk for VT/VF and recurrences over time. A series of modifying influences contribute to individual expression. (Modified from Myerburg RJ: Implantable cardioverter-defibrillators after myocardial infarction. *N Engl J Med* 359:2245, 2008.)

with nonobstructive hypertrophic cardiomyopathy are also at risk for SCD suggests that an electrophysiologic mechanism secondary to the hypertrophied muscle itself plays a major role. In athletes younger than 35 years, hypertrophic cardiomyopathy is the most common cause of SCD, in contrast to athletes older than 35 years, in whom ischemic heart disease is the most common cause.

Nonischemic Cardiomyopathy and Systolic and Diastolic Heart Failure

The advent of therapeutic interventions that provide better long-term control of congestive heart failure has improved the long-term survival of these patients (see Chapters 23, 25, and 65). However, the proportion of patients with heart failure who die suddenly is substantial, especially among those who appear clinically stable (i.e., functional class I or II).⁴⁴ The mechanism of SCD (VT or VF versus bradyarrhythmia or asystole) appears to be related to the cause (i.e., ischemic versus nonischemic). The absolute risk for SCD increases with deteriorating left ventricular function, but the ratio of sudden to nonsudden deaths is inversely related to the extent of functional impairment.⁴⁴ In patients with cardiomyopathy who have good functional capacity (Classes I and II), total mortality risk is considerably lower than in those with poor functional capacity (Classes III and IV), but the probability that a death will be sudden is higher (Fig. 39-9). Unexplained syncope has been observed to be a powerful predictor of SCD in patients who have functional class III or IV symptoms, regardless of the cause of cardiomyopathy. Ambulatory ventricular arrhythmias do not appear to indicate specific risk for SCD in such patients.

Diastolic heart failure with a preserved ejection fraction is being recognized as a condition that has a risk for mortality over time similar to that of heart failure with a reduced ejection fraction⁶⁸ (see Chapter 27). Although there are suggestions that risk for SCD in diastolic heart failure parallels that associated with systolic heart failure, possibly modulated by other risk factors,⁶⁹ additional studies are needed to clarify this relationship and its implication for medical practice.

The interaction between post-myocardial infarction ventricular arrhythmia and depressed ejection fraction in determining risk for SCD has been described. The most common causative basis for the association between chronic heart failure and SCD is ischemic cardiomyopathy. The prevalence of ischemic cardiomyopathy has been increasing because of better acute myocardial infarction survival statistics coupled with late remodeling. Other causes include idiopathic, alcoholic, and postmyocarditis congestive cardiomyopathies and the familial pattern of dilated cardiomyopathy, many of the latter

being associated with lamin A/C mutations.⁷⁰ Other gene loci have also been implicated. In addition, peripartum cardiomyopathy (see Chapter 78) may cause SCD.

Acute Heart Failure

All causes of acute cardiac failure (see Chapters 22 and 24), in the absence of prompt interventions, can result in SCD as a result of the circulatory failure itself or secondary arrhythmias. The electrophysiologic mechanisms involved have been proposed to be caused by acute stretching of ventricular myocardial fibers or the His-Purkinje system on the basis of its experimentally demonstrated arrhythmogenic effects. However, the roles of neurohumoral mechanisms and acute electrolyte shifts have not been fully evaluated. Among the causes of acute cardiac failure associated with SCD are massive acute myocardial infarction, acute myocarditis, acute alcoholic cardiac dysfunction, acute pulmonary edema in any form of advanced heart disease, and a number of mechanical causes of heart failure, such as massive pulmonary embolism, mechanical disruption of intracardiac structures secondary to infarction or infection, and ball valve embolism in aortic or mitral stenosis (see Table 39-5).

Inflammatory, Infiltrative, Neoplastic, and Degenerative Diseases of the Heart

Almost all diseases in this category have been associated with SCD, with or without concomitant cardiac failure. Acute viral myocarditis with left ventricular dysfunction (see Chapters 65 and 69) is commonly associated with cardiac arrhythmias, including potentially lethal arrhythmias.⁷¹ Serious ventricular arrhythmias or SCD can occur in patients with myocarditis in the absence of clinical evidence of left ventricular dysfunction.⁷² In a report of 19 SCDs in 1,606,167 previously screened U.S. Air Force recruits, 8 of 19 victims (42%) had evidence of myocarditis (5 nonrheumatic, 3 rheumatic) at postmortem examination, and 15 of 19 (79%) suffered their cardiac arrests during strenuous exertion. Sixty-eight percent of SCDs related to myocarditis in a study from Sweden had no premortem symptoms¹⁵ (Fig. 39-10), and most data available suggest a bias toward victims younger than 35 years, both for absolute numbers and for percentages of SCD caused by myocarditis.⁷³ Giant cell myocarditis and acute necrotizing eosinophilic myocarditis are particularly virulent for both myocardial damage and arrhythmias.⁷¹ Viral myocarditis can also cause damage isolated to the specialized conducting system and result in a propensity to arrhythmias; the rare association of this process with SCD has been reported. Varicella in adults is a rare cause of striking conduction system disorders, but left ventricular function is usually preserved; its relationship to SCD is unclear.

Myocardial involvement in collagen-vascular disorders, tumors, chronic granulomatous diseases, infiltrative disorders, and protozoan infestations varies widely, but SCD can be the initial or terminal manifestation of the disease process in all cases. Among the granulomatous diseases, sarcoidosis stands out because of the frequency of SCD associated with it. It has been reported that SCD was the terminal event in 67% of deaths attributable to sarcoid heart disease. The risk for SCD has been related to the extent of cardiac involvement, but ambient arrhythmias, such as nonsustained VT, may indicate risk in such patients with lesser degrees of cardiac involvement. In a report of the pathologic findings in nine patients who died of progressive systemic sclerosis, eight who died suddenly had evidence of transient ischemia and reperfusion histologically, thus suggesting that this might represent Raynaud-like involvement of the coronary vessels. Amyloidosis of the heart (see Chapter 65) may also cause sudden death. An incidence of 30% has been reported, and diffuse involvement of ventricular muscle or the specialized conducting system may be associated with SCD.

FIGURE 39-9 Risk for SCD related to left ventricular ejection fraction (EF) and functional classification in heart failure (HF). The relative probability of death being sudden is higher and absolute mortality risk is lower in patients with higher ejection fractions and better functional capacity. (Modified from Cleland JG, Chattopadhyay S, Khand A, et al: Prevalence and incidence of arrhythmias and sudden death in heart failure. *Heart Fail Rev* 7:229, 2002, with permission from Springer Science and Business Media.)

FIGURE 39-10 SCD in adolescents and young adults in Sweden. The frequency of preceding symptoms in 181 cases of SCD in persons 15 to 35 years old is shown by diagnostic group. ARVD = arrhythmogenic right ventricular dysplasia. (Modified from Wisten A, Forsberg H, Krantz P, Messner T: Sudden cardiac death in 15-35-year olds in Sweden during 1992-99. *J Intern Med* 252:529, 2002.)

Arrhythmogenic Right Ventricular Dysplasia or Right Ventricular Cardiomyopathy. This condition is associated with a high incidence of ventricular arrhythmias, including polymorphic nonsustained VT and VF and recurrent sustained monomorphic VT (see Chapters 32 and 37). Although symptomatic monomorphic VT has been well recognized in the syndrome for many years, the risk for SCD had been unclear and thought to be relatively low until the risks associated with the disease were clarified by a number of subsequent studies. In a high proportion of victims, perhaps as many as 80%, the first manifestation of the disease is “unexplained” syncope or SCD. SCD is often exercise related, and in some areas of the world where screening for hypertrophic cardiomyopathy has excluded affected athletes from competition, right ventricular dysplasia has emerged as the most common cause of sports-related SCD. Although it is generally considered a right ventricular abnormality, with possible late involvement of the left ventricle in advanced cases, a left ventricle–dominant pattern has also been described.⁷⁴

The genetic basis for right ventricular dysplasia has been explored because a large proportion of the cases have a familial distribution. The inheritance pattern is autosomal dominant, except in one geographically isolated cluster in which it is autosomal recessive (Naxos disease, plakoglobin locus on chromosome 17). Four loci encoding desmosome structure (plakoglobin, desmoplakin, plakophilin 2, and desmoglein 2) are collectively the most common known mutations associated with right ventricular dysplasia.⁷⁵⁻⁷⁷ Autosomal dominant mutations have also been identified in the ryanodine receptor locus on chromosome 1 (1q42) (see Chapter 32).

Valvular Heart Disease. Before the advent of surgery for valvular heart disease (see Chapter 63), severe aortic stenosis was associated with high risk for mortality. Approximately 70% of deaths were sudden and accounted for an absolute SCD mortality rate of 15% to 20% among all affected patients. A retrospective observational study of 133 asymptomatic patients with normal left ventricular function and severe aortic stenosis, defined as a peak aortic gradient of greater than 60 mm Hg, observed without surgery, identified 7 patients with SCDs (5%) during a mean follow-up of 3.3 years. Three of the deaths were preceded by a change in status: onset of dyspnea, decreasing left ventricular function, and a coronary event.⁷⁸ The advent of aortic valve replacement has reduced the incidence, but patients with prosthetic or heterograft aortic valve replacements remain at some risk for SCD caused by arrhythmias, prosthetic valve dysfunction, or coexistent coronary heart disease. The incidence peaks 3 weeks after surgery and then levels off after 8 months. A high incidence of ventricular arrhythmia has been observed during the follow-up of patients with valve replacement, especially those who had aortic stenosis, multiple valve surgery, or cardiomegaly. Sudden death during follow-up was associated with ventricular arrhythmias and thromboembolism. Stenotic lesions of other valves imply a much lower risk for SCD. Regurgitant lesions, particularly chronic aortic regurgitation and acute mitral regurgitation, may cause SCD, but the risk is also lower than with aortic stenosis.

Mitral Valve Prolapse. This entity is prevalent, but probably less so than previously thought, and is associated with a high incidence of annoying low-risk cardiac arrhythmias (see Chapter 63). However, the risk for SCD is apparent, although low. This uncommon complication appears to correlate best with marked redundancy of mitral leaflets seen on echocardiography, in conjunction with nonspecific ST-T wave changes in inferior leads on the electrocardiogram. Reported associations between QT interval prolongation or preexcitation and SCD in mitral prolapse syndrome are less consistent.

Endocarditis of the Aortic and Mitral Valves. This condition may be associated with rapid death resulting from acute disruption of the valvular apparatus (see Chapter 64), coronary embolism, or abscesses of valvular rings or the septum; however, such deaths are rarely true sudden deaths because conventionally defined tachyarrhythmic mechanisms are uncommon. Coronary embolism from valvular vegetations can trigger fatal ischemic arrhythmia on rare occasion.

Congenital Heart Disease. The congenital lesions most commonly associated with SCD are aortic stenosis (see Chapter 62) and communications between the left and right sides of the heart with the Eisenmenger physiology. In the latter, the risk for SCD is a function of the severity of pulmonary vascular disease; also, pregnant patients with Eisenmenger syndrome have an extraordinarily high risk for maternal mortality during labor and delivery (see Chapter 78).⁷⁹ Potentially lethal arrhythmias and SCD have been described as late complications after surgical repair of complex congenital lesions, particularly tetralogy of Fallot, transposition of the great arteries, and

atrioventricular (AV) canal defects. These patients should be observed closely and treated aggressively when cardiac arrhythmias are identified, although the late risk for SCD may not be as high as previously thought.

Electrophysiologic Abnormalities

Acquired disease of the AV node and His-Purkinje system and the presence of accessory pathways of conduction (see Chapter 37) are two groups of structural abnormalities of specialized conduction that may be associated with SCD. Clinical surveillance and follow-up studies have suggested that intraventricular conduction disturbances in coronary heart disease are one of the few factors that can increase the proportion of SCD in patients with coronary heart disease. Several studies from the late 1970s and the 1980s had demonstrated a very high risk for total mortality and SCD during the late in-hospital course and the first few months after hospital discharge in patients with anterior myocardial infarctions and right bundle branch or bifascicular block. In a later study evaluating the impact of thrombolytic therapy versus the pre-thrombolytic era experience, the incidence of pure right bundle branch block was higher but that of bifascicular block was lower, as were late complications and mortality. These observations suggest that the increased risk in those in whom advanced conduction abnormalities develop (probably related to infarct size) is not fully attenuated by thrombolytic therapy.

Primary fibrosis (Lenègre disease) or injury secondary to other disorders (Lev disease) of the His-Purkinje system is commonly associated with intraventricular conduction abnormalities and symptomatic AV block and less commonly with SCD. Identification of those at risk and the efficacy of pacemakers for prevention of SCD, rather than only amelioration of symptoms, have been subjects of debate. However, survival appears to depend more on the nature and extent of the underlying disease than on the conduction disturbance itself.

Patients with congenital AV block (see Chapter 37) or nonprogressive congenital intraventricular block, in the absence of structural cardiac abnormalities and with a stable heart rate and rhythm, have been characterized as being at low risk for SCD in the past. Later data have suggested that patients with the patterns of congenital AV block previously thought to be benign are at risk for dilated cardiomyopathy,⁸⁰ and routine pacemaker implantation in patients older than 15 years, if not indicated sooner, has been suggested by at least one group. Hereditary forms of AV heart block have also been reported in association with a familial propensity to SCD. Sodium channel gene mutations have been associated with progressive conduction system disturbances, along with aging, and some are variants of Brugada gene expression.^{81,82} External ophthalmoplegia and retinal pigmentation with progressive conduction system disease (Kearns-Sayre syndrome), which is associated with mitochondrial DNA variants, may lead to high-grade heart block and pacemaker dependence.

The anomalous pathways of conduction in Wolff-Parkinson-White syndrome are commonly associated with nonlethal arrhythmias. However, when the anomalous pathways of conduction have short anterograde refractory periods, the occurrence of atrial fibrillation may allow the initiation of VF during very rapid conduction across the accessory pathway (see Chapter 37). Patients who have multiple pathways appear to be at higher risk for SCD, as do patients with a familial pattern of anomalous pathways and premature SCD. The family history is relevant because a genetic predisposition to Wolff-Parkinson-White syndrome has been suggested.⁸³

Long-QT Syndromes. Congenital long-QT syndrome is a functional abnormality usually caused by inherited mutations affecting the molecular structure of ion channel proteins and is associated with environmental or neurogenic triggers that can initiate symptomatic or lethal arrhythmias (see Chapters 32 to 37).⁸⁴ Less commonly but not rarely, such mutations may occur de novo or may be transmitted from an apparently normal mosaic parent.⁸⁵ Two hereditary patterns have been described: the much more common autosomal dominant pattern known as the Romano-Ward syndrome and a rare autosomal recessive inheritance pattern associated with deafness, the Jervell and Lange-Nielsen syndrome. There is a broad range of phenotypic expression, with syncope being the most common manifestation in symptomatic

patients. SCD is less common, although data are limited by the absence of information on the number of undiagnosed carriers in whom fatal cardiac arrest is the first clinical event. Some patients have prolonged QT intervals throughout life without any manifest arrhythmias, whereas others are highly susceptible to symptomatic and potentially fatal ventricular arrhythmias, particularly the torsades de pointes pattern of VT.^{86,87} Moreover, the relationship between low penetrance and risk for SCD remains undefined, but such patients may be susceptible to the QT-lengthening effects of drugs or variations in serum electrolyte levels, expressed clinically as acquired long-QT syndrome (see later).

Higher levels of risk are associated with female sex, greater degrees of QT prolongation or QT alternans, unexplained syncope, family history of premature SCD, and documented torsades de pointes or previous VF. Patients with the syndrome require avoidance of drugs that are associated with QT lengthening and careful medical management, which may include implantable defibrillators. Moreover, it is important to identify and to manage relatives medically who carry the mutation and may be at risk (see Chapters 32 and 35 to 39). Mutations at loci on chromosomes 3, 7, and 11 (*KCNQ1*, *KCNH2*, *SCN5A*) and on chromosome 21 that encode the corresponding beta subunits (*KCNE1*, *KCNE2*, *SCN4B*) have been implicated in various patterns of the Romano-Ward and Jervell and Lange-Nielsen syndromes. Additional loci have been linked with less common genetic variants associated with a long QT interval. Another form of long-QT syndrome, LQT4, is associated with a mutation at a locus on chromosome 4 encoding the cytoskeletal element ankyrin-B⁸⁸ (see Chapters 32 and 37).

From an epidemiologic perspective, there is interest in whether QT interval abnormalities or the propensity thereto, interacting with acquired diseases, predisposes to SCD as a specific clinical expression.^{2,39} In a prospective cohort study of a population with a mean age of 69 years at entry, a prolonged QTc emerged as a powerful risk factor for SCD in the presence of cardiovascular disorders such as myocardial infarction, hypertension, and heart failure.⁸⁹ The hypothesis that common genetic variants may modulate QTc in unselected populations has stimulated interest in the relationship to selective risk for SCD in individuals with acquired diseases.²⁶ However, a number of rare variants may be even more important.

The acquired form of prolonged-QT interval syndrome refers to excessive lengthening of the QT interval and the potential for the development of torsades de pointes in response to environmental influences. Like congenital long-QT syndrome, it is more common in women. The syndrome may be caused by drug effects or an individual patient's idiosyncrasies (particularly related to class IA or III antiarrhythmic drugs and psychotropic drugs; see

Chapter 86), electrolyte abnormalities, hypothermia, toxic substances, bradyarrhythmia-induced QT adjustments, and central nervous system injury (most commonly subarachnoid hemorrhage). It has also been reported in intensive weight reduction programs that involve the use of liquid protein diets and in patients with anorexia nervosa. Lithium carbonate can prolong the QT interval and has been reported to be associated with an increased incidence of SCD in cancer patients with preexisting heart disease. Drug interactions have been recognized as a mechanism of prolongation of the QT interval and torsades de pointes. A growing body of evidence has suggested that inherited polymorphisms or mutations with low penetrance involving the same gene loci associated with phenotypically expressed long-QT syndrome underlie the so-called individual idiosyncrasies to the acquired form in many if not most cases.⁹⁰ In acquired prolonged-QT syndrome, as in the congenital form, torsades de pointes is commonly the specific arrhythmia that triggers or degenerates into VF.

Short-QT Syndrome. A familial pattern of risk for SCD has been associated with abnormally short QT intervals, defined as a QTc shorter than 300 milliseconds (QT <280 milliseconds) (see Chapters 32 and 37).⁹¹ Short-QT syndrome is much less common than long-QT syndrome, and there is little to guide risk profiling other than documented life-threatening arrhythmias and familial clustering of SCD.⁷² Several ion channel gene loci variants have been suggested.⁹²

Brugada Syndrome. This disorder is characterized by an atypical right bundle branch block pattern and unusual forms of nonischemic ST-T wave elevations in the anterior precordial leads (Fig. 39-11). It is a familial disorder associated with risk for SCD and occurs most commonly in young and middle-aged men (see Chapters 32 and 37). Mutations involving the cardiac Na⁺ channel gene (*SCN5A*) are the most commonly observed variants but are identified in only a minority of cases. Additional data demonstrate a number of other ion channel defects associated with the syndrome.⁹³ The right bundle branch block and ST-T wave changes may be intermittent and evoked or exaggerated by Na⁺ channel blockers (e.g., flecainide, procainamide). Individual risk for SCD is difficult to predict. Persistent type I electrocardiographic patterns, syncope, life-threatening arrhythmias, and a strong family history of SCD, in various combinations, are thought to be the best predictors.^{94,95} The reliability and added value of inducibility of VTs during programmed electrical stimulation studies are controversial.⁹⁶⁻⁹⁸ It appears to be of no value in patients with type III electrocardiographic patterns, of limited if any value in those with type II patterns, but may be of some value in selected patients with type I patterns or those who vary between type I and II, with or without provocation studies.

In a prospective registry in Italy,⁹⁹ Priori and colleagues evaluated the predictive accuracy of sustained VT/VF inducibility to identify

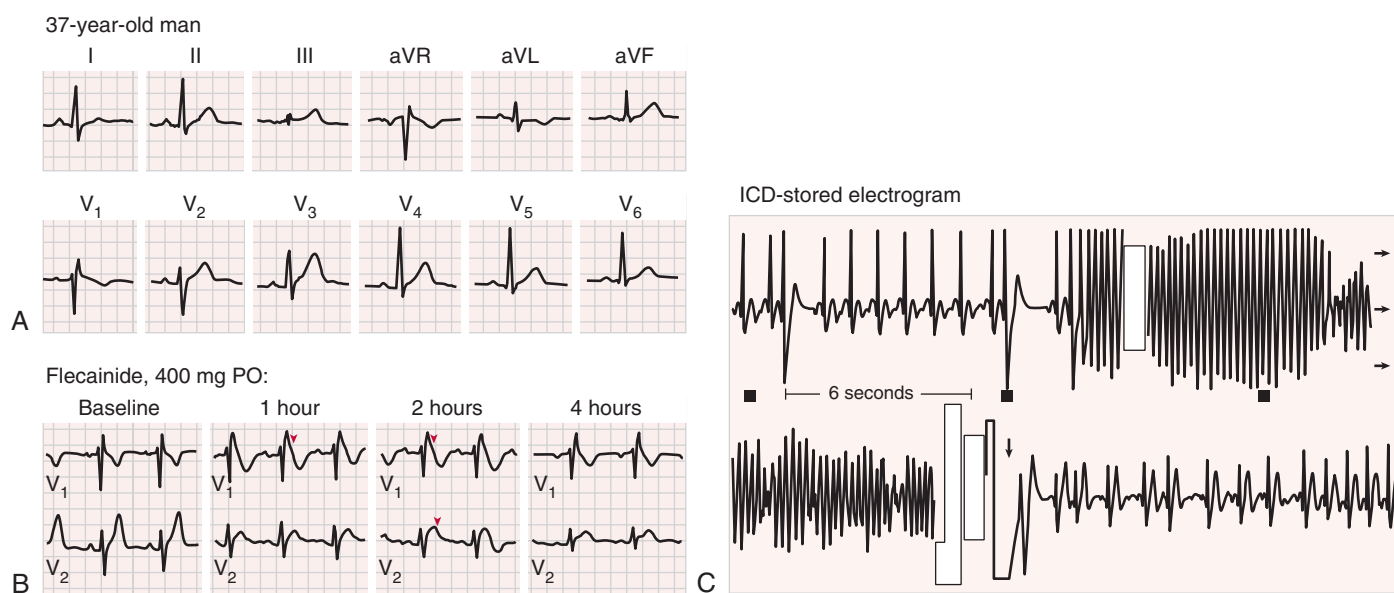

FIGURE 39-11 Electrocardiographic and clinical findings in a 37-year-old man with Brugada syndrome. The patient was resuscitated after out-of-hospital VF. No structural disease was identified. **A**, The 12-lead electrocardiogram shows an incomplete right bundle branch block pattern, which is not typical of Brugada syndrome. **B**, The typical repolarization changes associated with Brugada syndrome (arrowheads) were elicited by a single oral dose of flecainide, 400 mg. The patient received an ICD and 6 months later had an appropriate shock (arrow, **C**), as shown on the accompanying electrogram stored in the device.

patients considered to be at high risk for sudden death and who might be candidates for a prophylactic ICD. A total of 308 individuals with a spontaneous or drug-induced type I electrocardiographic pattern but without a history of SCA underwent programmed electrical stimulation at enrollment, and patients were evaluated every 6 months. After a median follow-up of 34 months, 14 arrhythmic events occurred, including 13 appropriate shocks of the ICD and 1 cardiac arrest. Programmed electrical stimulation using a standardized protocol induced VT/VF in 40% of the patients. An induced arrhythmia was not a significant predictor of events at follow-up. A spontaneous type I electrocardiographic pattern plus a history of syncope was an independent predictor of arrhythmic outcomes, as was an effective ventricular refractory period of less than 200 milliseconds and QRS fragmentation.

Early Repolarization and Sudden Cardiac Death. An association between the electrocardiographic pattern of early repolarization (ER) and risk for idiopathic VF has been described¹⁰⁰ (see Chapter 37). ER was limited to the inferior and lateral leads, in contrast to the anterior leads, which were used for the conventional definition of benign ER. The magnitude of J point elevation was significantly greater in cardiac arrest survivors than in controls with ER. Interestingly, a number of the clinical features were similar to the responses seen in patients with Brugada syndrome, thus leading to speculation whether the reported cases of VF associated with ER might be another expression of the Brugada pathophysiologic process.¹⁰¹

An association between ER and risk for SCD was observed in a long-term surveillance study in Finland.¹⁰² The observation that excess risk is expressed later in life suggests a possible interaction between the physiology of ER and acquired diseases, such as coronary heart disease. Risk was also associated with the presence of horizontal or downsloping ST-segments with ER in the inferior leads.¹⁰³

Catecholaminergic Polymorphic Ventricular Tachycardia. Catecholaminergic polymorphic VT is an inherited syndrome associated with catecholamine-dependent lethal arrhythmias in the absence of forewarning electrocardiographic abnormalities and with at least partial control by beta adrenoceptor-blocking agents (see Chapters 32 and 37). An autosomal dominant pattern involving the ryanodine receptor locus (RyR2) was initially described predominantly in younger patients, usually men, with bidirectional or polymorphic VT associated with risk for SCD. A pattern not associated with that genotype appeared to be more likely in older patients (young adults), usually women. More recent data suggest less dominance by male sex for RyR2 variants and another variant involving autosomal recessive inheritance of calsequestrin loci (CASQ2) in approximately 10% of genotyped cases and relatives.¹⁰⁴

Electrical Instability Resulting from Neurohumoral and Central Nervous System Influences. Several central nervous system-related interactions with cardiac electrical stability have been suggested (see Chapters 33 and 89). Epidemiologic data have also suggested an association between behavioral abnormalities and risk for SCD. Psychological stress and emotional extremes have been suggested for many years to be triggering mechanisms for advanced arrhythmias and SCD,¹⁰⁵ but only limited, largely observational data support such associations (see Chapter 86). Acute emotional stress has been reported to be a cause of a specific form of reversible left ventricular dysfunction and heart failure characterized by ballooning of the apex with a narrow neck at the base of the heart (termed takotsubo cardiomyopathy, named for the similarity of this shape to a Japanese octopus fishing pot).^{106,107} It is suspected to be catecholamine mediated and its long-term prognosis is good, but the short-term risk for SCD during the acute phase remains uncertain.

Stress-induced arrhythmias are better supported than stress-induced risk for mortality, which requires further study. Data from the 1994 Los Angeles earthquake identified an increased rate of fatal cardiac events on that day, but the event rate was reduced during the ensuing 2 weeks, thus suggesting triggering of events about to happen rather than independent causation.¹⁰⁸ Associations between auditory stimulation and auditory auras and SCD have been reported. Auditory abnormalities in some forms of congenital QT prolongation have also been observed.

A variant of torsades de pointes characterized by short coupling intervals between a normal impulse and the initiating impulse has been described (Fig. e39-1). It appears to have familial trends and to be related to alterations in autonomic nervous system activity. The 12-lead electrocardiogram demonstrates normal QT intervals, but VF and sudden death are common (see Chapters 32 and 37).

The phenomenon of voodoo death has been studied in pockets of isolation in underdeveloped countries. There appears to be an

association between isolation from the tribe, a sense of hopelessness, severe bradyarrhythmias, and sudden death. Limited clinical observations and experimental data modeling voodoo death have suggested a mechanism related to parasympathetic overactivity, as opposed to the evidence of an adrenergic basis for syndromes related to acute emotional stress.

Sudden Infant Death Syndrome and Sudden Cardiac Death in Children

SIDS occurs between birth and 6 months of age, is more common in male infants, and had an incidence of 1.2 deaths per 1000 live births before widespread publication of appropriate sleep positions in at-risk infants.¹⁰⁹ Between 1992 and 2002, the incidence fell to 0.57 death per 1000 live births as attention to sleep position grew, thus supporting a major role for obstructive sleep apnea as a mechanism. Vulnerability as a result of various mechanisms of dysfunctional central respiratory control, both inherent and related to prematurity, is likely to interact with sleep position as a multicomponent mechanism.¹¹⁰

Because of its abrupt nature, a primary cardiac mechanism had been suspected as the basis of this syndrome in some victims for many years, and a large study of electrocardiograms of infants has suggested an association of risk for SIDS with prolonged QT intervals. Subsequently, a near-miss survivor was shown to have a de novo mutation of the Na⁺ channel gene (SCN5A; chromosome 3), which provided proof of concept that a long QT may be one mechanism of SIDS. The relative incidence of SIDS in victims with longer QT intervals and documentation of additional long-QT-related arrhythmias in near misses have supported the notion that as many as 15% of cases of SIDS may occur by this mechanism. Other cardiac causes have also been reported. Accessory pathways (two cases) and dispersed or immature AV nodal or bundle branch cells in the annulus (four cases) have been described.

Sudden death in children beyond the SIDS age group and in adolescents and young adults is associated with identifiable heart disease in most cases. Approximately 25% of cases of SCDs in children occur in those who have undergone previous surgery for congenital cardiac disease. Of the remaining 75%, more than half occur in children who have one of four lesions: congenital aortic stenosis, Eisenmenger syndrome, pulmonary stenosis or atresia, or obstructive hypertrophic cardiomyopathy (see Chapter 62). Other common causes included myocarditis, hypertrophic and dilated cardiomyopathy, congenital heart disease, and aortic dissection.

Sudden Cardiac Death in Competitive and Recreational Athletes and During Intense Exercise

SCD can occur during or after extreme physical activity in competing athletes or under special circumstances in the general population. Examples of the latter include intense conditioning exercise and basic military training. Among adolescent and young adult competitive athletes, the incidence was estimated to be in the range of 1 per 75,000 annually in Italy, as opposed to less than 1 per 125,000 for the general nonathlete population in the same age group. In a survey of high school athletes in Minnesota, the frequency of sudden unexpected death related to cardiovascular disease during competitive sports was reported to be approximately 1 per 100,000 individual student athlete participants, a figure similar to that in the general population in that age group.¹¹¹ Exercise-related incidence figures are more difficult to ascertain in other populations, but one study reported an incidence of one SCD per 1.5 million exercise sessions in health clubs.⁴⁷ The incidence of exercise-related cardiac arrest appears to be lower in women.¹¹² Most athletes and nonathletes have a previously known or unrecognized cardiac abnormality. In middle-aged and older adults, in whom coronary disease dominates as the cause of SCD, exercise-related deaths appear to be associated with acute plaque disruption. Whether exercise contributed to the initiation of plaque disruption or preexisting disruption simply set the stage for the fatal response during exercise remains unclear. Among athletes, hypertrophic cardiomyopathy with or without obstruction and occult congenital or acquired coronary artery disease are the most common causes identified after death (see Chapter 79),¹¹³ with myocarditis contributing a significant minority. In a report of a large cohort of U.S.

FIGURE e39-1 Short-coupled variant of torsades de pointes. This variant has been observed in people without structural heart disease and with normal QT intervals. They are subject to spontaneous episodes of polymorphic ventricular tachycardia (torsades de pointes), which may degenerate into VF. This uncommon syndrome is associated with a high risk for sudden death.

Air Force recruits, a surprisingly large fraction of those who died suddenly during exertion had unsuspected myocarditis. Diseases attributed to molecular structural abnormalities, such as long-QT syndrome and right ventricular dysplasia, are increasingly being recognized as causes of SCD in athletes and exercising nonathletes. Blunt chest wall trauma by sports objects, such as baseballs and hockey pucks, can initiate lethal arrhythmias, a syndrome known as commotio cordis (see Chapter 79).¹¹⁴

Attention to recreational athletics and high-level conditioning activities is emerging. A 5-year survey of sports-related SCD and resuscitated SCA among the general population in France was based on a prospective, comprehensive survey of subjects 10 to 75 years old.¹¹⁵ The investigators detected an incidence of 4.6 cases per million population per year, with only 6% of cases occurring in young competitive athletes. The remainder occurred during recreational athletic activities, most commonly cycling, jogging, or soccer. Analysis of suspected underreporting suggested that the incidence of sports-related sudden death throughout France might be as high as 5 to 17 new cases per million population per year. Case subjects were predominantly male (95%) and had no previous history of heart disease. The mean age was 46 years. Just more than half (51.9%) of the sports-related SCDs occurred in public sports venues, and 99.8% of them were witnessed. However, bystander cardiopulmonary resuscitation (CPR) was performed in only 35.5% of cases.

A study of SCA risk in marathon and half-marathon runners suggested that the overall incidence did not appear to be higher than that for the general population in the age group of participants.¹¹⁶ The most commonly identified causes were hypertrophic cardiomyopathy, with or without other disorders, and coronary artery disease.

Sudden death from true cardiac causes in athletes should not be confused with precipitous death related to heat stroke or malignant hyperthermia. In the latter, the victim has usually exercised excessively in hot weather, often with athletic gear that impairs heat dissipation and sometimes in association with the use of substances that cause heat production and vasoconstriction impairing heat exchange. This leads to collapse with markedly elevated core body temperatures and, ultimately, irreversible organ system damage. Ingestion of exogenous dietary supplements, particularly ephedrine and caffeine-containing preparations in excessive quantities, has been proposed to have a role in the precipitation of life-threatening arrhythmias, largely on the basis of case report data. As a result, the U.S. Food and Drug Administration (FDA) has banned marketing of these substances for enhancement of athletic performance or weight loss.

Other Causes and Circumstances Associated with Sudden Death

A small group of victims has neither previously determined functional abnormality nor identifiable structural abnormalities at postmortem examination. Such events or deaths, when they are associated with documented VF, are classified as idiopathic. Although long-term survival after an idiopathic, potentially fatal event is still unclear, some degree of risk appears to remain. The idiopathic category is decreasing as the subtle molecular causes become better defined, including recognition by postmortem genetic studies. Limited data suggest that higher risk persists primarily in patients with subtle cardiac structural abnormalities, in contrast to patients who are truly normal. In addition, these events tend to occur in young, otherwise healthy people.

A number of non-cardiac-related conditions can also cause or mimic SCD. Sleep apnea is associated with a risk for nocturnal death, including deaths attributable to cardiac causes. The risk for death peaks during the night rather than in the early morning hours.¹⁷ Another respiratory system-based cause of sudden death is the so-called café coronary, in which food lodges in the oropharynx and causes an abrupt obstruction at the glottis. The holiday heart syndrome is characterized by cardiac arrhythmias, most commonly atrial, as well as other cardiac abnormalities associated with acute alcoholic states. It has not been determined whether potentially lethal arrhythmias occurring in such settings account for the reported sudden deaths associated with acute alcoholic states. Massive pulmonary embolism (see Chapter 73) can cause acute cardiovascular collapse and sudden death; sudden death in severe acute asthmatic attacks, without prolonged deterioration of the patient's condition, is well recognized. Air or amniotic fluid embolism at the time of labor and delivery may cause sudden death on rare occasion, with the clinical picture mimicking that of SCD. Peripartum air embolism caused by unusual sexual practices has been reported as a cause of such sudden deaths.

Finally, a number of abnormalities that do not directly involve the heart may cause sudden deaths that mimic SCD. Such abnormalities include aortic dissection (see Chapter 57), acute cardiac tamponade (see Chapter 71), and rapid exsanguination. The electrical mechanism associated with these deaths is most commonly severe bradyarrhythmias, pulseless electrical activity (PEA), or asystole rather than ventricular tachycardia or fibrillation.

PATHOLOGY AND PATHOPHYSIOLOGY

Pathologic studies in SCD victims reflect the epidemiologic and clinical observations that coronary atherosclerosis is the major predisposing cause. In one report, 81% of 220 victims of SCD had significant coronary heart disease at autopsy. At least one vessel with more than 75% stenosis was found in 94% of the victims, acute coronary occlusion in 58%, healed myocardial infarction in 44%, and acute myocardial infarction in 27%. These observations are consistent with subsequent studies of the frequency of coronary disease in SCD victims, but the focus has evolved from the simple anatomic presence of coronary lesions to specific associations with unstable plaque. All other causes of SCD (see Table 39-5) collectively account for no more than 15% to 20% of cases, but they have provided a large base of enlightening pathologic data.

Pathology of Sudden Death Caused by Coronary Artery Abnormalities

Coronary Arteries. Extensive atherosclerosis has long been recognized as the most common pathologic finding in the coronary arteries of victims of SCD. The combined results of a number of studies have suggested a general pattern of at least two coronary arteries with 75% or greater narrowing in more than 75% of the victims. Several studies have demonstrated no specific pattern of distribution of coronary artery lesions that preselect for SCD. In a quantitative analysis comparing coronary artery narrowing at postmortem examination in SCD victims and control subjects, 36% of the 5-mm segments of the coronary arteries from the SCD group had 76% to 100% reductions in cross-sectional area as compared with 3% in the control group. An additional 34% of sections from the SCD group had 51% to 75% reductions in cross-sectional area. Only 7% of sections from the SCD patients had 0% to 25% reductions in cross-sectional area.

The role of active coronary artery lesions, characterized by plaque fissuring, plaque erosion or rupture, platelet aggregation, and thrombosis, as a major pathophysiologic mechanism of the onset of cardiac arrest has become clarified (see Chapter 51). Among 100 consecutive victims of sudden coronary death, 44% had major (>50% luminal occlusion) recent coronary thrombi, 30% had minor occlusive thrombi, and 21% had plaque fissuring. Only 5% had no acute coronary artery changes; 65% of the thrombi occurred at sites of preexisting high-grade stenoses, and an additional 19% were found at sites with greater than 50% stenosis. In a subsequent study, 50 (30%) of 168 victims had occlusive intraluminal coronary thrombi, and 73 (44%) had mural intraluminal thrombi. Single-vessel disease, acute infarction at postmortem examination, and prodromal symptoms were associated with the presence of thrombi. In a later study, plaque rupture or erosion was observed in 66% of the culprit vessel lesions in victims of SCD related to coronary heart disease. Disruption, platelet aggregation, and thrombosis are associated with markers of inflammation and various conventional risk factors for coronary atherosclerosis, such as cigarette smoking and hyperlipidemia.

Some of the less common, nonatherosclerotic coronary artery abnormalities have specific pathologic features as well. Coronary artery spasm, an established cause of acute ischemia and SCD, is commonly associated with nonobstructive plaque (Fig 39-12), and spasm itself has been recognized at postmortem examination in rare cases. When deep myocardial bridges are identified in association with SCD, patchy fibrosis in areas subserved by the affected vessel is commonly seen at postmortem examination. Coronary vasculitis in association with various autoimmune disorders may cause diffuse myocardial abnormalities, but asymptomatic cardiac involvement or global myocardial dysfunction is more common than SCD.

Myocardium. Myocardial injury in SCD caused by coronary heart disease reflects the extensive atherosclerosis usually present. Studies of victims of out-of-hospital SCD and from epidemiologic sources have

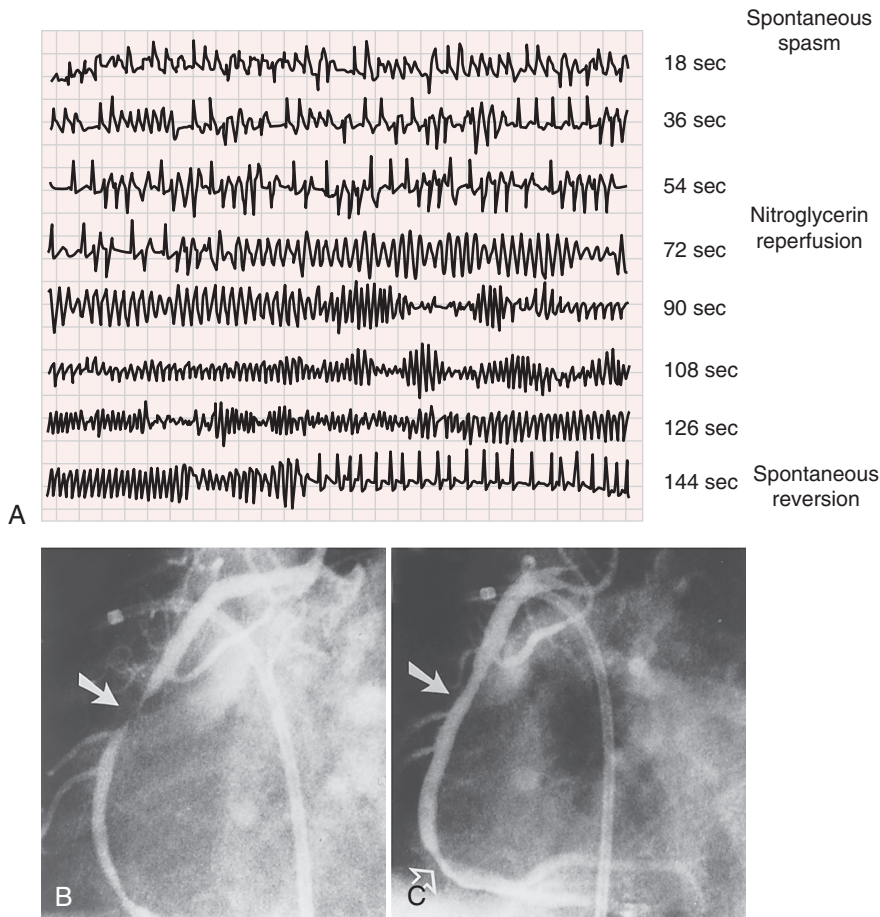

FIGURE 39-12 Life-threatening ventricular arrhythmias associated with acute myocardial ischemia related to coronary artery spasm and with reperfusion. **A**, Continuous lead II electrocardiographic monitor recording during ischemia (time, 0 to 55 seconds) caused by spasm of the right coronary artery (**B**). Following the administration of nitroglycerin at approximately 55 seconds, an abrupt transition from repetitive ventricular ectopy to a rapid polymorphic, prefibrillatory tachyarrhythmia occurs (time, 80 to 130 seconds) in association with reversal of the spasm (**C**). Closed arrows indicate the site of spasm before and after nitroglycerin; the open arrow indicates a lower grade distal lesion. (Modified from Myerburg RJ, Kessler KM, Mallon SM, et al: Life-threatening ventricular arrhythmias in patients with silent myocardial ischemia due to coronary artery spasm. *N Engl J Med* 326:1451, 1992.)

indicated that healed myocardial infarction is a common finding in SCD victims, with most investigators reporting frequencies ranging from 40% to more than 70%. In one study, 72% of men in the 25- to 44-year age group who died suddenly (≤ 24 hours) with no previous clinical history of coronary heart disease had scars of large (63%) or small (<1 -cm cross-sectional area, 9%) areas of healed myocardial necrosis. The incidence of acute myocardial infarction is considerably lower, with cytopathologic evidence of recent myocardial infarction found in an average of approximately 20% of individuals. This estimate corresponds well with the results of studies of out-of-hospital cardiac arrest survivors, who were found to have an incidence of new myocardial infarction in the range of 20% to 30%. These pathologic observations do not provide insight into the likely possibility that many SCDs occur as a result of acute coronary syndrome mechanisms and progress from ischemia to fatal arrhythmias without time for structural markers to become visible. Even though there is an association between elevations in troponin levels during chest pain syndromes and risk for subsequent cardiac death and although increases in troponin levels are seen in a substantial proportion of cardiac arrest survivors, the question of whether the myocardial injury preceded or resulted from the cardiac arrest is difficult to resolve in individual cases.

Ventricular Hypertrophy. Myocardial hypertrophy can coexist and interact with acute or chronic ischemia but appears to confer an independent risk for mortality. No close correlation has been found between increased heart weight and the severity of coronary heart disease in SCD victims; however, heart weight is higher in SCD victims than in those whose death is not sudden despite a similar prevalence of a history of hypertension before death. Risk for hypertrophy-associated

mortality is also independent of left ventricular function and the extent of coronary artery disease, and left ventricular hypertrophy itself may predispose to SCD. Experimental data have also suggested increased susceptibility to potentially lethal ventricular arrhythmias in patients with left ventricular hypertrophy and ischemia and reperfusion. A study of massively enlarged hearts (i.e., weighing more than 1000 g), however, did not indicate an excess incidence of SCD, but the underlying pathologic process in that study was dominated by lesions that produce volume overload.

Specialized Conducting System in Sudden Cardiac Death. Fibrosis of the specialized conducting system may be observed in SCD victims. Although this process is associated with AV block or intraventricular conduction abnormalities, its role in SCD is uncertain. Lev disease, Lenègre disease, ischemic injury caused by small-vessel disease, and numerous infiltrative or inflammatory processes can result in such changes. In addition, active inflammatory processes such as myocarditis and infiltrative processes such as amyloidosis, scleroderma, hemochromatosis, and morbid obesity may damage or destroy the AV node, bundle of His, or both and result in AV block.¹¹⁷

Focal diseases such as sarcoidosis, Whipple disease, and rheumatoid arthritis and fibrotic or fatty infiltration of the AV node or His-Purkinje system with apparent discontinuities can also involve the conducting system (see Chapter 37). These various categories of conducting system disease have been considered possible pathologic substrates for SCD that might be overlooked because of the difficulty of performing careful postmortem examinations of the conducting system routinely. Focal involvement of conducting tissue by tumors (especially mesothelioma of the AV node but also lymphoma, carcinoma, rhabdomyoma, and fibroma) has also been reported, and rare cases of SCD have been associated with these lesions. It has been suggested that abnormal postnatal morphogenesis of the specialized conducting system may be a significant factor in some cases of SCD in infants and children.

Cardiac Nerves and Sudden Cardiac Death. Diseases of cardiac nerves have been postulated to have a role in SCD (see Chapter 89). Neural involvement may be the result of random damage to neural elements within the myocardium (i.e., secondary cardioneuropathy) or may be primary, as in a selective cardiac viral neuropathy. Secondary involvement can be a consequence of ischemic neural injury in coronary heart disease and has been proposed to result in autonomic destabilization, thereby enhancing the propensity to arrhythmias. Nerve sprouting may be important.¹¹⁸ Some experimental data have supported this hypothesis, and a clinical technique for imaging of cardiac neural fibers suggests a changing pattern over time after myocardial infarction. Viral, neurotoxic, and hereditary causes (e.g., progressive muscular dystrophy and Friedreich ataxia) have been emphasized.

Mechanisms and Pathophysiology

Electrical mechanisms of cardiac arrest are divided into tachyarrhythmic and bradyarrhythmic-asystolic events. The tachyarrhythmias include VF and pulseless or sustained VT, in which adequate blood flow cannot be maintained and perfusion is inadequate to meet the body's needs. Bradyarrhythmic-asystolic events include severe bradyarrhythmias, dissociation between spontaneous electrical activity and mechanical function (PEA), and inability to generate a mechanical event because of complete absence of electrical activity (asystole). To qualify as a mechanism of cardiac arrest, severe bradyarrhythmias must be slow enough to result in an inability to adequately perfuse and maintain consciousness, which usually

requires a heart rate of less than 20 beats/min. In PEA, the electrical rate can be considerably faster, but there is no perfusion because of inadequate or absent mechanical activity or mechanical obstruction to blood flow, as in massive pulmonary embolism. It is likely that many victims found to be asystolic at contact were initially in VF or VT. After a variable time, fibrillation may cease and asystole or PEA emerges. In contrast to earlier data, the most common initial recording documented in recent years is asystole or PEA, which can continue as such or very rarely transform into VF.

The occurrence of potentially lethal tachyarrhythmias or severe bradyarrhythmia or asystole is the end of a cascade of pathophysiologic abnormalities that result from complex interactions between coronary vascular events, myocardial injury, variations in autonomic tone, and the metabolic and electrolyte state of the myocardium (see Fig. 39-6).¹¹ There is no uniform hypothesis of mechanisms by which these elements interact to lead to the final pathway of lethal arrhythmias. However, Figure 39-8 shows models of the pathophysiologic process of SCD that include vascular, myocardial, and functional components. The risk for cardiac arrest is conditioned by the presence of structural abnormalities and modulated by functional variations.

Pathophysiologic Mechanisms of Lethal Tachyarrhythmias

Coronary Artery Structure and Function. Among the 80% of SCDs associated with coronary atherosclerosis, an extensive distribution of chronic arterial narrowing has been well defined by pathologic studies. However, the specific mechanisms by which these lesions lead to potentially lethal disturbances in electrical stability are not simply the consequence of steady-state reductions in regional myocardial blood flow in association with variable demands (see Chapter 41).^{10,11} A simple increase in myocardial oxygen demand, in the presence of a fixed supply, may be a mechanism of exercise-induced arrhythmias and sudden death during intense physical activity or in others whose heart disease had not previously become clinically manifested. However, the dynamic nature of the pathophysiologic mechanism of coronary events has led to the recognition that superimposed acute lesions create a setting in which alterations in the metabolic or electrolyte state of the myocardium are the common circumstance leading to disturbed electrical stability. Active vascular events resulting in an acute or transient reduction in regional myocardial blood flow in the presence of a normal or previously compromised circulation constitute a common mechanism of ischemia, angina pectoris, arrhythmias, and SCD. Coronary artery spasm or modulation of coronary collateral flow, predisposed to by local endothelial dysfunction, exposes the myocardium to the double hazard of transient ischemia and reperfusion (see Fig. 39-12). Neurogenic influences may play a role but do not appear to be a *sine qua non* for the production of spasm. Vessel susceptibility and humoral factors, particularly those related to platelet activation and aggregation, also appear to be important mechanisms.

Transition of stable atherosclerotic plaque to an “active” state because of endothelial damage, with plaque fissuring leading to platelet activation and aggregation followed by thrombosis, is a mechanism that appears to be present in most SCDs related to coronary heart disease (see Chapter 54). Inflammatory responses in atherosclerotic plaque are now viewed as the condition leading to lesion progression, including erosion, disruption, platelet activation, and thrombosis. In addition to causing a subacute or acute critical reduction in regional blood flow, these mechanisms produce a series of biochemical alterations that may enhance or retard susceptibility to VF by means of vasomotor modulation.

The final step in the role of coronary artery pathophysiology leading to ischemia-induced arrhythmias can be platelet aggregation and thrombosis (see Figs. 39-6 and 39-8; see Chapter 41). The discrepancy between the relatively high incidence of acute thrombi in post-mortem studies and the low incidence of evolution of new myocardial infarction in survivors of out-of-hospital VF highlights this point. The rapid initiation of lethal arrhythmias, the spontaneous thrombolysis, a dominant role of spasm induced by platelet products, or a combination of these factors may explain this observation.

Acute Ischemia and Initiation of Lethal Arrhythmias. The onset of acute ischemia produces immediate electrical, mechanical,

and biochemical dysfunction of cardiac muscle. The specialized conducting tissue is more resistant to acute ischemia than working myocardium is, and therefore the electrophysiologic consequences are less intense and delayed in onset in specialized conduction tissue. In addition to the direct effect of ischemia on normal or previously abnormal tissue, reperfusion after transient ischemia can cause lethal arrhythmias (see Fig. 39-12). Reperfusion of ischemic areas can occur by three mechanisms: (1) spontaneous thrombolysis, (2) collateral flow from other coronary vascular beds to the ischemic bed, and (3) reversal of vasospasm. Some mechanisms of reperfusion-induced arrhythmogenesis appear to be related to the duration of ischemia before reperfusion. Experimentally, there is a window of vulnerability beginning 5 to 10 minutes after the onset of ischemia and lasting up to 20 to 30 minutes.

Electrophysiologic Effects of Acute Ischemia. Within the first minutes after experimental coronary ligation, there is a propensity to ventricular arrhythmias that abates after 30 minutes and reappears after several hours (see Chapter 33). The initial 30 minutes of arrhythmias is divided into two periods, the first of which lasts for approximately 10 minutes and is presumably directly related to the initial ischemic injury. The second period (20 to 30 minutes) may be related either to reperfusion of ischemic areas or to the evolution of different injury patterns in epicardial and endocardial muscle. Multiple mechanisms of reperfusion arrhythmias have been observed experimentally, including slow conduction and reentry and afterdepolarizations and triggered activity.

At the level of the myocyte, the immediate consequences of ischemia, which include alterations in cell membrane physiology, with efflux of K^+ , influx of Ca^{2+} , acidosis, reduction of transmembrane resting potentials, and enhanced automaticity in some tissues, are followed by a separate series of changes during reperfusion. Those of particular interest are the possible continued influx of Ca^{2+} , which may produce electrical instability; responses to alpha or beta adrenoceptor stimulation, or both; and afterdepolarizations as triggering responses for Ca^{2+} -dependent arrhythmias. Other possible mechanisms studied experimentally include the formation of superoxide radicals in reperfusion arrhythmias and differential responses of endocardial and epicardial muscle activation times and refractory periods during ischemia or reperfusion. The adenosine triphosphate-dependent K^+ current ($I_{K,ATP}$), which is inactive during normal conditions, is activated during ischemia. Its activation results in a strong efflux of K^+ ions from myocytes and markedly shortening of the time course of repolarization, which leads to slow conduction and ultimately to inexcitability. The fact that this response is more marked in epicardium than in endocardium leads to a prominent dispersion of repolarization across the myocardium during transmural ischemia. At an intercellular level, ischemia alters the distribution of connexin 43, the primary gap junction protein between myocytes.¹¹⁹ This alteration results in uncoupling of myocytes, a factor that is arrhythmogenic because of altered patterns of excitation and regional changes in conduction velocity.¹²⁰

The state of the myocardium at the time of onset of ischemia is important. Tissue healed after previous injury appears to be more susceptible to the electrical destabilizing effects of acute ischemia, as is chronically hypertrophied muscle. Some data suggest that remodeling-induced local stretch, regional hypertrophy, or intrinsic cellular alteration may contribute to this vulnerability. Of more direct clinical relevance is the suggestion that potassium depletion by diuretics and clinical hypokalemia may make ventricular myocardium more susceptible to potentially lethal arrhythmias.

The association of metabolic and electrolyte abnormalities and neurophysiologic and neurohumoral changes with lethal arrhythmias emphasizes the importance of integrating changes in the myocardial substrate with systemic influences. Most direct among myocardial metabolic changes in response to ischemia are local acute increase in interstitial K^+ levels to values exceeding 15 mM, a decrease in tissue pH to below 6.0, changes in adrenoceptor activity, and alterations in autonomic nerve traffic, all of which tend to create and maintain electrical instability, especially if it is regional in distribution. Other metabolic changes, such as elevation of cyclic adenosine monophosphate levels, accumulation of free fatty acids and their metabolites, formation of lysophosphoglycerides, and impaired myocardial glycolysis, have also been suggested as myocardial-destabilizing influences.¹²¹ These local myocardial changes integrate with systemic patterns of autonomic fluctuation that can be observed as patterns of altered heart rate variability and fractal dynamics,¹²² thus potentially identifying subsets of patients predetermined to be at higher risk for SCD during an ischemic event.

Transition from Myocardial Instability to Lethal Arrhythmias

The combination of a triggering event and a susceptible myocardium is a fundamental electrophysiologic concept for the mechanism of initiation of potentially lethal arrhythmias (see Figs. 39-6 and 39-8). The triggering event may be electrophysiologic, ischemic, metabolic, or hemodynamic. The endpoint of their interaction is disorganization of patterns of myocardial activation into multiple uncoordinated reentrant pathways (i.e., VF). Clinical, experimental, and pharmacologic data have suggested that triggering events in the absence of myocardial instability are unlikely to initiate lethal arrhythmias. Therefore, in the absence of myocardial vulnerability, many triggering events, such as frequent and complex PVCs, may be innocuous.

Bradyarrhythmias and Asystolic Arrest

The basic electrophysiologic mechanism in this form of arrest is failure of normal subordinate automatic activity to assume the pace-making function of the heart in the absence of normal function of the sinus node, AV junction, or both. Asystolic arrest is more common in severely diseased hearts and in patients with a number of end-stage disorders, cardiac and noncardiac. These mechanisms may result, in part, from diffuse involvement of subendocardial Purkinje fibers in advanced heart disease.

Pulseless Electrical Activity

PEA, formerly called electromechanical dissociation, is separated into primary and secondary forms. No one unifying definition for PEA, mechanistically or clinically, is recognized. The common denominator in both is the presence of organized cardiac electrical activity in the absence of effective mechanical function.¹²³ The absence of rapid spontaneous return of circulation is important in that it excludes transient losses of cerebral blood flow, such as the various patterns of vasovagal reflex syncope, which have different clinical implications than the meaning attributed to true PEA. The secondary form of PEA includes causes that result from an abrupt cessation of cardiac venous return, such as massive pulmonary embolism, acute malfunction of prosthetic valves, exsanguination, and cardiac tamponade from hemopericardium. The primary form is the more familiar; in this form none of these obvious mechanical factors is present, but ventricular muscle fails to produce an effective contraction despite continued electrical activity (i.e., failure of electromechanical coupling). It usually occurs as an end-stage event in advanced heart disease, but it can occur in patients with acute ischemic events or, more commonly, after electrical resuscitation from prolonged cardiac arrest. Although it is not thoroughly understood, it appears that diffuse disease, metabolic abnormalities, or global ischemia provides the pathophysiologic substrate. The proximate mechanism for failure of electromechanical coupling may be abnormal intracellular Ca^{2+} metabolism, intracellular acidosis, or perhaps depletion of ATP.

CLINICAL FEATURES OF PATIENTS WITH CARDIAC ARREST

Although the pathologic anatomy associated with SCD caused by coronary artery disease often reflects the changes associated with acute myocardial injury, only one in five survivors of out-of-hospital VF has clinical evidence of a new transmural myocardial infarction. Nonetheless, many have elevations in enzyme levels along with nonspecific electrocardiographic changes suggesting myocardial damage, which may be caused by transient ischemia as a triggering event or be a consequence of the loss of myocardial perfusion during the cardiac arrest. The former supports the concept of transient pathophysiologic changes (such as a transient platelet plug) associated with acute coronary syndromes as the trigger for cardiac arrest. The recurrence rate is low in survivors of out-of-hospital cardiac arrest caused by documented transmural myocardial infarction. In

contrast, early studies demonstrated a 30% recurrence rate at 1 year and 45% at 2 years in the survivors who did not have a new transmural myocardial infarction. Recurrence rates decreased subsequently, probably in part the result of long-term interventions. However, it is not known whether the decrease resulted from a change in the natural history, changes in preventive strategies for the underlying disease, or long-term interventions for control of arrhythmic risk.

Clinical cardiac arrest and SCD can be described in the framework of the same four phases of the event used to establish temporal definitions (see Fig. 39-1): prodromes, onset of the terminal event, cardiac arrest, and progression to biologic death or survival.

Prodromal Symptoms

Patients at risk for SCD can have prodromes such as chest pain, dyspnea, weakness or fatigue, palpitations, syncope, and a number of nonspecific complaints. Several epidemiologic and clinical studies have demonstrated that such symptoms can presage coronary events, particularly myocardial infarction and SCD, and result in contact with the medical system weeks to months before SCD.

Attempts to identify early prodromal symptoms specific for risk for SCD have not been successful. Although several studies have reported that 12% to 46% of fatalities occur in patients who had seen a physician 1 to 6 months before death, such visits are more likely to presage myocardial infarction or nonsudden death, and most complaints responsible for these visits are not heart related. However, patients who have chest pain as a prodrome to SCD appear to have a higher probability of intraluminal coronary thrombosis at postmortem examination. Fatigue has been a particularly common symptom in the days or weeks before SCD in a number of studies, but this symptom is nonspecific. The symptoms that occur within the last hours or minutes before cardiac arrest are more specific for heart disease and may include symptoms of arrhythmias, ischemia, and heart failure.

Onset of the Terminal Event

The period of 1 hour or less between acute changes in cardiovascular status and the cardiac arrest itself is defined as the "onset of the terminal event." Ambulatory recordings fortuitously obtained during the onset of an unexpected cardiac arrest have indicated dynamic changes in cardiac electrical activity during the minutes or hours before the event. Increasing heart rate and advancing grades of ventricular ectopy are common antecedents of VF. Alterations in autonomic nervous system activity may also contribute to onset of the event. Studies of short-term variations in heart rate variability or related measures have identified changes that correlate with the occurrence of ventricular arrhythmias. Although these physiologic properties may be associated with transient electrophysiologic destabilization of the myocardium, the extent to which they are paralleled by clinical symptoms or events has been less well documented.¹²² SCDs caused by arrhythmias or acute circulatory failure mechanisms correlate with a high incidence of acute myocardial disorders at the onset of the terminal event; such disorders are more likely to be ischemic when the death is caused by arrhythmias and to be associated with low-output states or myocardial anoxia when the deaths are caused by circulatory failure.

Abrupt, unexpected loss of effective circulation can be caused by cardiac arrhythmias or mechanical disturbances, but most such events that terminate in SCD are arrhythmic.

Cardiac Arrest

Cardiac arrest is characterized by abrupt loss of consciousness caused by lack of adequate cerebral blood flow as a result of failure of cardiac pump function. It almost always leads to death in the absence of a successful intervention, although spontaneous reversions occur rarely. The most common electrical mechanism is VF, followed by asystole or PEA and pulseless VT. Mechanical mechanisms include rupture of the ventricle, cardiac tamponade, acute mechanical obstruction to flow, and acute disruption of a major blood vessel.

The potential for successful resuscitation is a function of the setting in which the cardiac arrest occurs, the mechanism of the arrest, and the underlying clinical status of the victim. Closely related to the potential for successful resuscitation is the decision regarding whether to attempt to resuscitate.¹²⁴

At present, there are fewer low-risk patients with otherwise uncomplicated myocardial infarctions weighting in-hospital cardiac arrest statistics than occurred previously. In one report, only 14% of patients receiving in-hospital CPR were discharged from the hospital alive, and 20% of these patients died within the ensuing 6 months. Although 41% of the patients had suffered an acute myocardial infarction, 73% had a history of congestive heart failure and 20% had experienced previous cardiac arrests. The mean age of 70 years may have influenced the outcome statistics, but patients with high-risk complicated myocardial infarction and those with other high-risk markers heavily influenced the population of patients at risk for in-hospital cardiac arrest. Non-cardiac-related clinical diagnoses were dominated by renal failure, pneumonia, sepsis, diabetes, and a history of cancer. The strong male preponderance consistently reported in out-of-hospital cardiac arrest studies is not present in in-hospital patients, but the better prognosis of VT or VF mechanisms than PEA or asystolic mechanisms persists (27% versus 8% survival rate). However, the proportion of arrests caused by in-hospital VT or VF is considerably less (33%), with the combination of respiratory arrest, asystole, and PEA dominating the statistics (61%). In another report, a 22% survival rate to hospital discharge was observed. Adverse risks were age older than 70 years, previous stroke or renal failure, and heart failure on admission. Better outcomes were predicted by previous angina pectoris or admission because of ventricular arrhythmias. Strategic factors affecting survival after in-hospital cardiac arrest include the location in the hospital, the type of hospital, daytime and evening events versus night and weekend events, and a rapid time to performance of defibrillation.¹²⁵

A multihospital study of outcomes after in-hospital cardiac arrest in pediatric patients demonstrated a major improvement in survival to hospital discharge between 2000 and 2009, with a risk-adjusted improvement from 14.3% in 2000 to 43.4% in 2009.¹²⁶ There was neither improvement nor worsening of the proportion with residual neurologic deficits. The proportion with VF or pulseless VT decreased from 22% in 2000 to 2003 to 9.7% in 2007 to 2009, and those with asystole decreased from 51.4% to 20%. In contrast, PEA increased from 26.6% to 70.3%. The reason for the dramatic increase in the proportion of PEA events is not clear because respiratory insufficiency as an initial condition increased only from 68.8% to 75.5%. However, the proportion maintained on mechanical ventilators at the time of arrest did increase from 67.4% (2000 to 2003) to 81.6% (2007 to 2009).

Important risk factors for death after CPR are listed in **Table 39-6**. The fraction of out-of-hospital cardiac arrest survivors who are discharged from the hospital alive may now equal or exceed the fraction of in-hospital cardiac arrest victims who are discharged alive, and the postdischarge mortality rate for in-hospital cardiac arrest survivors is higher than that for out-of-hospital cardiac arrest survivors; these are telling clinical statistics. They emphasize the success of preventive measures for cardiac arrest in low-risk in-hospital patients, a finding indicating that these statistics are dominated by higher risk patients. However, other data demonstrate that survival after in-hospital cardiac arrest is lower for events that occur during weeknights and weekends than during the daytime and evening hours during the week¹²⁵ and that more rapid times to defibrillation are advantageous.¹²⁷ Such data suggest the need for additional strategies for uniformly rapid in-hospital responses.

Among elderly persons, outcomes after community-based responses to out-of-hospital cardiac arrest are not as good as for younger victims. In one study comparing persons younger than 80 years (mean age, 64 years) with those in their 80s and 90s, the survival rate to hospital discharge in the younger group was 19.4% as opposed to 9.4% for octogenarians and 4.4% for nonagenarians.¹²⁸ However, when the groups were analyzed according to markers favoring survival (e.g., VF, pulseless VT), the incremental benefit was even better for the elderly than for the younger patients (36%, 24%, and

TABLE 39-6 Predictors of Mortality after In-Hospital Cardiopulmonary Resuscitation

Modified from Bedell SE, Delbanco TL, Cook EF, Epstein FH: Survival after cardiopulmonary resuscitation in the hospital. *N Engl J Med* 309:569, 1983.

17%, respectively), but the frequency of ventricular tachyarrhythmias versus nons Shockable rhythms was lower in elderly persons. Overall, advanced age is only a weak predictor of an adverse outcome and should not be used in isolation as a reason to not resuscitate. Long-term neurologic status and length of hospitalization were similar in older and younger surviving patients.

Progression to Biologic Death

The time course for progression from cardiac arrest to biologic death is related to the mechanism of the cardiac arrest, the nature of the underlying disease process, and the delay between onset and resuscitative efforts. The onset of irreversible brain damage usually begins within 4 to 6 minutes after loss of cerebral circulation, and biologic death follows quickly in unattended cardiac arrest. In large series, however, it has been demonstrated that a limited number of victims can remain biologically alive for longer periods and may be resuscitated after delays in excess of 8 minutes before beginning basic life support and in excess of 16 minutes before advanced life support. Despite these exceptions, it is clear that the probability of a favorable outcome—survival neurologically intact—deteriorates rapidly as a function of time after cardiac arrest. Younger patients with less severe cardiac disease and the absence of coexistent multisystem disease have a higher probability of a favorable outcome after such delays.

Irreversible injury to the central nervous system usually occurs before biologic death, and the interval may extend days to weeks and occasionally result in very prolonged persistent vegetative states in patients who are resuscitated during the temporal gap between brain damage and biologic death. In-hospital cardiac arrest caused by VF is less likely to have a protracted course between the arrest and biologic death, with patients surviving after a prompt intervention or succumbing rapidly because of inability to stabilize their cardiac rhythm or hemodynamics.

Patients whose cardiac arrest is caused by sustained VT with cardiac output inadequate to maintain consciousness can remain in VT for considerably longer periods with blood flow that is marginally sufficient to maintain viability. Thus there is a longer interval between the onset of cardiac arrest and the end of the period that allows successful resuscitation. The lives of such patients usually end in VF or asystolic arrest if the VT is not actively or spontaneously reverted. Once the transition from VT to VF or to a bradyarrhythmia has occurred, the subsequent course to biologic death is similar to that in patients in whom VF or bradyarrhythmias are the initiating event.

The progression in patients with asystole or PEA as the initiating event is more rapid. Such patients, whether in an in-hospital or out-of-hospital environment, have a poor prognosis because of advanced heart disease or coexistent multisystem disease. They tend to respond poorly to interventions, even if the heart is successfully paced. Although a small subgroup of patients with bradyarrhythmias

associated with electrolyte or pharmacologic abnormalities may respond well to interventions, most progress rapidly to biologic death. The infrequent cardiac arrests caused by mechanical factors such as tamponade, structural disruption, and impedance to flow by major thromboembolic obstructions to right or left ventricular outflow are reversible only in patients in whom the mechanism is recognized and an intervention is feasible. Most of these events lead to rapid biologic death, although prompt relief of tamponade-induced cardiac arrest will save some lives.

Survivors of Cardiac Arrest Hospital Course

Cardiac arrests during the acute phase of myocardial infarction are classified as *primary* (electrical event not associated with hemodynamic dysfunction) or *secondary* (electrical event linked to hemodynamic dysfunction). Patients who are resuscitated immediately from primary VF associated with acute coronary syndromes usually stabilize promptly, and they require no long-term arrhythmia management based on the early arrhythmia (see Chapter 55). Management after secondary cardiac arrest in patients with myocardial infarction is dominated by the hemodynamic status of the patient.

Survivors of out-of-hospital cardiac arrest may have repetitive ventricular arrhythmias during the initial 24 to 48 hours of hospitalization. These arrhythmias have variable responses to antiarrhythmic therapy, depending on hemodynamic status. The overall rate of recurrent cardiac arrest is low, 10% to 20%, but the mortality rate in patients who have recurrent cardiac arrests is approximately 50%. Only 5% to 10% of in-hospital deaths after out-of-hospital resuscitation are caused by recurrent cardiac arrhythmias. Patients with recurrent cardiac arrest have a high incidence of new or preexisting AV or intraventricular conduction abnormalities.

The most common causes of death in hospitalized survivors of out-of-hospital cardiac arrest are noncardiac events related to central nervous system injury, including anoxic encephalopathy and sepsis related to prolonged intubation and hemodynamic monitoring lines. Fifty-nine percent of deaths during the index hospitalization after out-of-hospital resuscitation have been reported to be from these causes. Approximately 40% of those who arrive at the hospital in coma never awaken after admission to the hospital and die after a median survival of 3.5 days. Two thirds of those who regain consciousness have no gross deficits, and an additional 20% have persisting cognitive deficits only. Of the patients who do awaken, 25% do so by admission, 71% by the first hospital day, and 92% by the third day. A small number of patients have awakened after prolonged hospitalization. Among those who die in the hospital, 80% do not awaken before death. Two studies have suggested a potential benefit of therapeutic hypothermia for patients with post-cardiac arrest coma (see later, Clinical Profile of Survivors of Out-of-Hospital Cardiac Arrest).^{128,129}

Cardiac causes of delayed death during hospitalization after out-of-hospital cardiac arrest are most commonly related to hemodynamic deterioration, which accounts for about a third of deaths in hospitals. Among all deaths, those that occurred within the first 48 hours of hospitalization were usually caused by hemodynamic deterioration or arrhythmias regardless of neurologic status; later deaths were related to neurologic complications. Admission characteristics most predictive of subsequent awakening included motor response, pupillary light response, spontaneous eye movement, and blood glucose level below 300 mg/dL.

Clinical Profile of Survivors of Out-of-Hospital Cardiac Arrest

The clinical features of survivors of out-of-hospital cardiac arrest are heavily influenced by the type and extent of the underlying disease associated with the event. Causation is dominated by coronary heart disease, which accounts for approximately 80% of out-of-hospital cardiac arrests in the United States⁸ and is commonly extensive. The cardiomyopathies collectively account for another 10% to 15%; all

other structural heart diseases plus functional abnormalities and toxic or environmental causes are responsible for the remainder.

In a study of 63 survivors of cardiac arrest with normal ejection fractions and no obvious heart disease, no cause was identified after intensive studies in 44% of the patients.¹³⁰ The remainder were found to have long-QT syndromes (23%), catecholaminergic polymorphic VT (23%), right ventricular dysplasia (17%), ER (14%), coronary spasm (11%), Brugada syndrome (9%), and myocarditis (3%). The mean age of this group was 43 years, and 46% had had no previous history of presyncope or syncope.

Left Ventricular Function. Left ventricular function is abnormal in most survivors of out-of-hospital cardiac arrest, often severely abnormal, but there is wide variation ranging from severe dysfunction to normal or almost normal measurements.¹³¹ The severity of myocardial dysfunction estimated shortly after cardiac arrest is due to a combination of myocardial stunning consequent to the cardiac arrest itself and the extent of preexisting dysfunction. Stunning commonly improves within the first 24 to 48 hours,¹³² and the residual is assumed to be due to preexisting disease or to the acute injury leading to the cardiac arrest. Reliance on postarrest troponin elevations alone to determine whether myocardial infarction caused a cardiac arrest can be treacherous because cardiac arrest and even non-life-threatening sustained arrhythmias can be associated with transient elevations.¹³³ If the ejection fraction is severely reduced initially, failure to begin improvement within the first 48 hours is an adverse short-term prognostic sign. In a study of resuscitated out-of-hospital cardiac arrest victims admitted to the hospital and subsequently discharged alive and neurologically intact, 47% had acute coronary syndromes identified during evaluation and had a mean ejection fraction of 42% as opposed to 32% in nonsurvivors.¹³⁴ Among survivors to hospital discharge, a reduced ejection fraction is an adverse long-term prognostic sign.

Coronary Angiography. Survivors of out-of-hospital cardiac arrest tend to have extensive coronary disease but no specific pattern of abnormalities. Acute coronary lesions, often multifocal, are present in most survivors.¹³⁰ Significant lesions in two or more vessels are present in at least 70% of patients who have any coronary lesion. In patients who have recurrent cardiac arrests, the incidence of triple-vessel disease is higher than in those who do not. However, the frequency of moderate to severe stenosis of the left main coronary artery does not differ between cardiac arrest survivors and the overall population of patients with symptomatic coronary heart disease.

Exercise Testing. Exercise testing is no longer commonly used to evaluate the need for and response to anti-ischemic therapy in survivors of out-of-hospital cardiac arrest, except when there is a question of transient ischemia as a mechanism for onset. The probability of a positive test result related to ischemia is relatively low, although termination of testing because of fatigue is common. Mortality during follow-up is higher in patients who fail to achieve a normal rise in systolic blood pressure during exercise.

Electrocardiographic Observations. Among survivors of out-of-hospital cardiac arrest, the 12-lead electrocardiogram (see Chapter 12) has proved to be of value only for discriminating risk for recurrence in those whose cardiac arrest was associated with new transmural myocardial infarction. Patients in whom documented new Q waves develop in association with a clinical picture that supports the assumption that an ST-segment elevation myocardial infarction began before the cardiac arrest itself are at lower risk for recurrence.¹ In contrast, nonspecific electrocardiographic markers of ischemia, associated with elevation of troponin or creatine kinase MB levels, indicate higher risk for recurrence. A higher incidence of repolarization abnormalities (e.g., ST-segment depression, flat T waves, prolonged QT) occurs in out-of-hospital cardiac arrest survivors than in post-myocardial infarction patients, and these might be markers for increased risk. A prolonged QRS duration in association with a markedly reduced ejection fraction portends increased risk for mortality.¹³⁵

Blood Chemistry. Lower serum potassium levels are observed in survivors of cardiac arrest than in patients with acute myocardial infarction or stable coronary heart disease. This finding is often a consequence of resuscitation interventions rather than a preexisting hypokalemic state because of chronic diuretic use or other causes. Low ionized calcium levels with normal total calcium levels were also observed during resuscitation from out-of-hospital cardiac arrest. Higher resting lactate levels have been reported in out-of-hospital cardiac arrest survivors than in normal subjects. Lactate levels correlated inversely with ejection fractions and directly with PVC frequency and complexity.

Long-Term Prognosis

Studies from the early 1970s had indicated that the risk for recurrent cardiac arrest in the first year after survival of an initial VT/VF event was approximately 30% and at 2 years was 45%. Total mortality at 2 years was approximately 60% in both studies. More recent mortality data,¹³⁶ including those from the control groups of secondary prevention ICD trials,⁷² have demonstrated 2-year mortality rates between 15% and 25%. The apparent improved outcomes, independent of the benefit provided by ICD therapy, are probably attributable to the current interventions used in survivors, such as beta adrenoceptor blockers, anti-ischemic procedures, and heart failure therapies that were not available or in general use at the earlier time. The risk for recurrent cardiac arrest and all-cause mortality is higher during the first 12 to 24 months after the index event and relates best to the ejection fraction during the first 6 months.

MANAGEMENT OF CARDIAC ARREST

The response to cardiac arrest is driven by two urgent principles: (1) maintenance of continuous artificial cardiopulmonary support until return of spontaneous circulation has been achieved and (2) restoration of spontaneous circulation as quickly as possible. To achieve these goals, the management strategy is divided into five elements: (1) initial assessment and summoning of an emergency response team, (2) basic life support, (3) early defibrillation by a first responder (if available), (4) advanced life support, and (5) post-cardiac arrest care. If successful, the algorithm is followed by a sixth element, long-term management. The initial elements can be applied by a broad array of responders, including physicians and nurses, as well

as paramedical personnel, emergency rescue technicians, and laypeople trained in bystander interventions. Requirements for specialized knowledge and skills increase progressively as the patient is moved through post-cardiac arrest management into long-term follow-up care. These emergency response principles are intended for both in-hospital application and community-based responses.

In-Hospital Interventions

Development of the coronary care unit provided an immediate reduction of in-hospital mortality risk during acute myocardial infarction from 30% to 15% based almost entirely on the effect on risk for cardiac arrest. As additional therapies emerged, mortality rates continued to fall. Other specialized monitoring and intensive care units demonstrated various levels of benefit as well, but the impact has been less in general care hospital units and for cardiac arrests associated with complex comorbid states.¹³⁷ A registry study in the decade from 2000 to 2009 provided trends for risk-adjusted rates of survival to discharge after cardiac arrest in monitored units and general hospital units.¹³⁸ Among 84,625 subjects, 20.7% had VF or pulseless VT as the initial rhythm and 79.3% had asystole or PEA, with the proportion of cardiac arrests attributable to asystole/PEA increasing over time ($P < 0.001$). The overall survival rate to discharge increased from 13.7% in 2000 to 22.3% in 2009 ($P < 0.001$), with improvement in both the VF/VT and the PEA/asystole subsets (**Fig. 39-13A**). Absolute rates of survival to discharge remained higher for the VT/VF group, whereas improvement in survival occurred in the two rhythm groups. The improvement in survival appeared to be due to both improved acute resuscitation actions and postresuscitation care. A small decrease in rates of clinically significant neurologic disability in survivors occurred over time (32.9% in 2000 and 28.1% in 2009 [$P = 0.02$]).

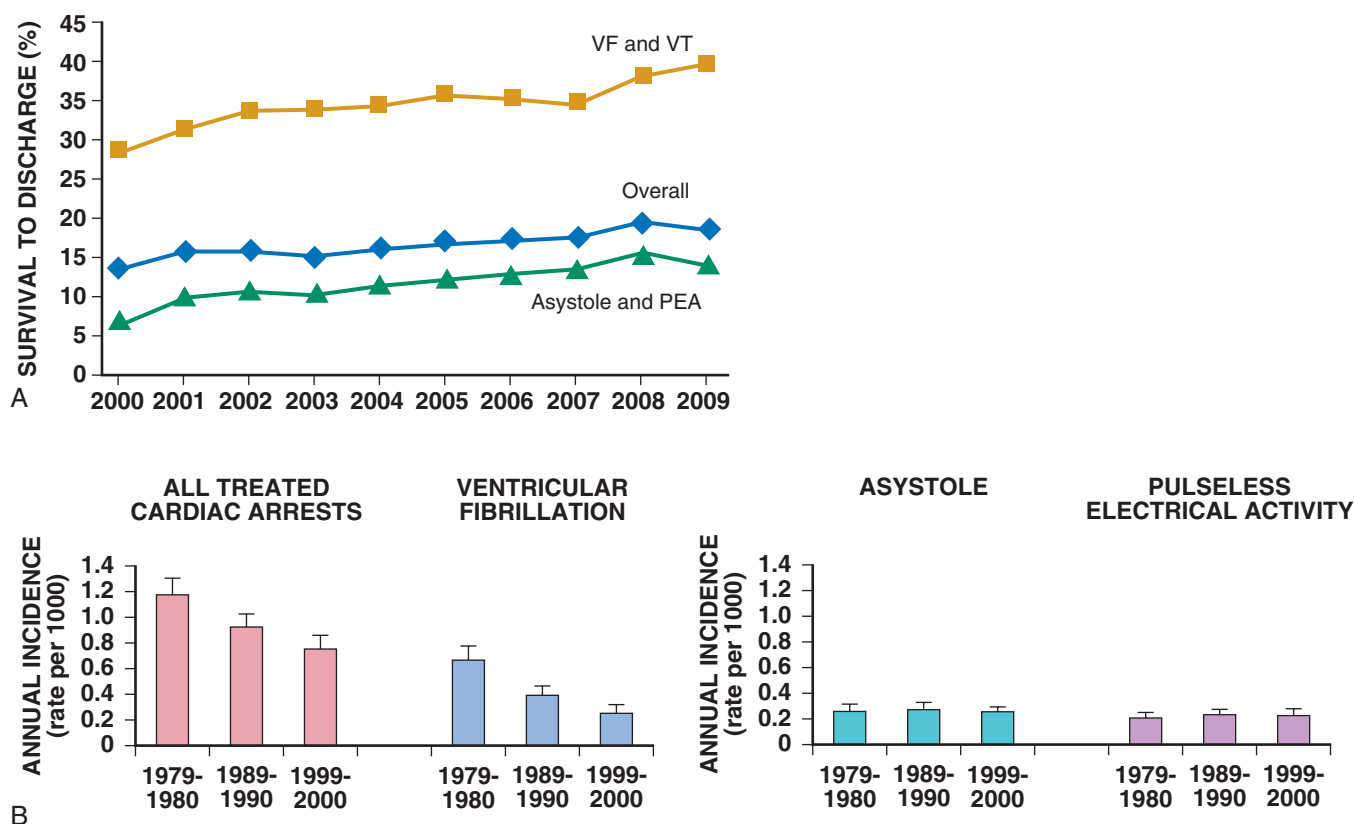

FIGURE 39-13 Changing incidence of shockable and nonshockable rhythms. **A**, Survival to discharge for VF and pulseless VT versus asystole and PEA between 2000 and 2009 ($P < 0.001$ for trend in each survival curve). **B**, Between 1980 and 2000 a progressive decrease in the VF event rate occurred in the Seattle, Wash., community for unexplained reasons. Of note is the fact that no concomitant increase in nonshockable rhythms took place. The proportion of events with VF at initial contact is decreasing, as observed in several other studies. (**A**, From Girotra S, Nallamothu BK, Spertus JA, et al: Trends in survival after in-hospital cardiac arrest. *N Engl J Med*, 367:1912, 2012; **B**, modified from Cobb LA, Fahrenbruch CE, Olsufka M, Copass MK: Changing incidence of out-of-hospital ventricular fibrillation, 1980-2000. *JAMA* 288:3008, 2002.)

Community-Based Interventions

The initial out-of-hospital intervention experience in Miami and Seattle yielded only 14% and 11% rates of survival to discharge, respectively (Fig. e39-2). Subsequent improvements correlated with the addition of emergency medical technicians as another tier of responders to provide CPR and earlier defibrillation. In general, rural areas have lower success rates, and the U.S. national success rate is probably 5% or less. Regional variability is highlighted by a 10-community analysis in the United States and Canada demonstrating a range of VF survival rates from 0% to 39.5%.⁹

Reports from different areas in the United States show marked variations in outcomes.¹³⁹ Some very densely populated areas (i.e., Chicago and New York City) have provided disturbing outcome data. A study from Chicago reported that only 9% of out-of-hospital cardiac arrest victims survive to be hospitalized and that only 2% are discharged alive. Moreover, outcomes in blacks are far worse than those in whites (0.8% versus 2.6%). The fact that a large majority had bradyarrhythmias, asystole, or PEA on initial contact with emergency medical services suggests prolonged times between collapse and arrival of the emergency medical service, absent or ineffective bystander interventions, or both. The New York City report indicated a survival to hospital discharge rate of only 1.4%. Among those who undergo bystander CPR, the rate increases to 2.9%, and bystander CPR plus VF as the initial rhythm yields a further increase to 5.3%. Finally, for those whose arrests occurred after the arrival of emergency medical services, the success rate increases further to 8.5%. These trends support the concept that delays and breaks in the "chain of survival"¹⁴⁰ have a major negative impact on the results of emergency medical services in densely populated areas.¹³⁹

There are circumstances in which resuscitative effort in the out-of-hospital setting is deemed futile. A victim found unconscious after an unwitnessed collapse, reasonably assumed to be found after a prolonged interval (e.g., cool skin, rigor mortis), obviously fulfills this classification. However, studies have provided markers of futility under less stark circumstances. In a study involving trained responders with automated external defibrillators (AEDs), only 0.5% of victims survived if (1) the arrest was not witnessed by emergency medical service personnel, (2) there was no return of spontaneous circulation, and (3) no shocks were delivered per protocol. Adding a response time

longer than 8 minutes reduced the survival rate to 0.3%, and events unwitnessed by a bystander yielded no survivors.¹⁴¹

Impact of Tiered Response Systems

Improvements in both out-of-hospital care and in-hospital technology and practices can contribute to better outcomes, as described in the chain-of-survival concept.¹⁴⁰ Of these two general factors, the influence of out-of-hospital care has been studied in more detail. The importance of early defibrillation for improving outcome has been supported by a number of studies (Fig. e39-3).¹⁴² These observations have motivated a search for strategies that shorten response times, largely by the development of two-tiered systems (Fig. 39-14) in which nonconventional first responders, such as police, firemen, security guards, and laypeople, deploy AEDs in public places.¹⁴³⁻¹⁴⁵ Preliminary data suggest that this strategy may improve outcome by substantial increments through the rationale of shortening response times, primarily in public locations (see Fig. 39-14).

In rural communities, earlier defibrillation by ambulance technicians yielded a 19% survival rate versus only 3% for standard CPR. In another report, an analysis of the relationship between response delay and survival to hospital discharge revealed a 48% survival rate for response times of 2 minutes or less and less than a 10% survival rate when responses were longer than 10 minutes (see Fig. 39-14). The mean response time was approximately 13 minutes, and the overall survival rate was 5%. It was 9.5% for those in VT or VF on first contact. A second element in out-of-hospital care that contributes to outcome is the role of bystander CPR by laypeople awaiting the arrival of emergency rescue personnel.^{142,146,147} It has been reported that although there was no significant difference in the percentage of patients successfully resuscitated and admitted to the hospital alive with (67%) or without (61%) bystander intervention, almost twice as many out-of-hospital cardiac arrest victims were ultimately discharged alive when they had undergone bystander CPR (43%) than when such support was not provided (22%). Central nervous system protection, expressed as early regaining of consciousness, is the major protective element of bystander CPR. The rationale for bystander intervention is further highlighted by the relationship between time to defibrillation and survival when analyzed as a function of time to initiation of basic CPR. It has been reported that more

FIGURE 39-14 Influence of response time on survival from out-of-hospital cardiac arrest. **A**, The time from the onset of cardiac arrest to the initial defibrillation attempt is related to 1-month survival on the basis of data from the Swedish Cardiac Arrest Registry. The cumulative survival rate was 5%, and the survival rate for victims whose initial rhythm was VT or VF was 9.5%. The median response time was nearly 13 minutes. Thirty-day survival rates ranged from a maximum of 48% with responses shorter than 2 minutes to less than 5% with response time longer than 15 minutes. **B**, Potential for faster response systems based on the Amsterdam Resuscitation Study. The response times of police vehicles are compared with those of conventional emergency medical systems (EMSs). At the 50th percentile of response times, police vehicles provided an almost 5-minute improvement in arrival time (≈ 6 minutes). (**A**, Modified from Holmberg M, Holmberg S, Herlitz J: The problem of out-of-hospital cardiac arrest: Prevalence of sudden death in Europe today. *Am J Cardiol* 83:88D, 1999; **B**, modified from Waalewijn RA, de Vos R, Koster RW: Out-of-hospital cardiac arrests in Amsterdam and its surrounding areas: Results from the Amsterdam resuscitation study [ARREST] in "Utstein" style. *Resuscitation* 28:157, 1998.)

HISTORY OF COMMUNITY-BASED EMERGENCY RESPONSE SYSTEMS

1971-1974	Initial Miami/Seattle outcomes	14%, 11%
1978-1985	Peak Miami/Seattle outcomes	25%-35%
1984	Rural outcomes:	
	• Standard basic life support	3%
	• Ambulance-based expanded access	19%
1991	Estimated cumulative U.S. survival	1%-3%
1992-1994	Major metropolitan population centers	2%
1996	Dade County, Florida, current outcomes	9%
1996-1998	Updated U.S. EMS outcomes, cumulative	<5%
1999	"Optimized" EMS systems [OPALS]	5%
2000-2004	Nonconventional responders:	17%->50%
	Public access sites [police, security guards, airline personnel, laypersons; airports and airliners, malls, casinos, stadiums]	

FIGURE e39-2 The history of out-of-hospital cardiac arrest survival statistics demonstrates that standard emergency rescue systems are not sufficient to have a meaningful impact on sudden cardiac death in the community. EMS = emergency medical system. (From Myerburg RJ: Sudden cardiac death: Exploring the limits of our knowledge. *J Cardiovasc Electrophysiol* 12:369, 2001.)

FIGURE e39-3 Impact of emergency rescue system design and immediate defibrillation on out-of-hospital cardiac arrest survival. **A**, Percent survival to hospital discharge with rescue activities by standard emergency medical technicians (EMTs) trained in CPR, EMTs allowed to defibrillate immediately (EMT_{defib}), initial response by paramedics (P-MED), two-tiered system with EMT and P-MED, and two-tiered system with EMTs allowed to defibrillate if they are the first responders plus P-MED. Training of first-responders (EMT_{defib}) and a two-tiered system have the best outcome. **B**, Comparison of outcomes observed in five geographic areas with EMTs providing only CPR (purple) versus EMTs trained to defibrillate as first responders (blue). Each group had a marked improvement in outcome when EMTs were trained and permitted to defibrillate. (Modified from Ornato JP, Orn A: Community experience in treating out-of-hospital cardiac arrest. In Akhtar M, Myerburg RJ, Ruskin JN [eds]: Sudden Cardiac Death: Prevalence, Mechanisms and Approach to Diagnosis and Management. Baltimore, Williams & Wilkins, 1994, p 450.)

than 40% of victims whose defibrillation and other advanced life support activities were instituted more than 8 minutes after collapse survived if basic CPR had been initiated less than 2 minutes after onset of the arrest. A period of CPR before defibrillation may also be helpful, particularly if the time to defibrillation exceeds 4 minutes from the onset of arrest.¹⁴⁷

Importance of Electrical Mechanisms

Several sources have identified a changing distribution of initial rhythms recorded by emergency rescue personnel. When compared with data from the 1970s and 1980s, there has been a decrease in the number of events in which ventricular tachyarrhythmias are the initial rhythm recorded, with a consequent reduction in the proportion of victims who have rhythms amenable to cardioversion-defibrillation (see Fig. 39-13B). Similar observations have been reported in in-hospital settings.^{138,148} Some studies have now suggested that less than 50% of victims have shockable rhythms at initial contact. This fact is associated with a reduction in cumulative survival probability with community-based interventions,⁵ even though data from studies using nonconventional AED strategies have suggested improvement of outcomes in VT or VF victims.¹⁴⁵ Because this finding does not appear to be related to time from the 911 summons to arrival, it is likely that pre-911 delays in recognition of and reaction to an event may be playing a role, which suggests a need for more extensive public education programs. Thus response times may not be as close to true downtimes as one would hope, and consequently the potential for success is impaired. The 4- to 6-minute time for a desirable response is not optimal. By 4 minutes, significant circulatory and ischemic changes have taken place, and conditions worsen rapidly beyond that time.¹⁴²

The electrical mechanism of out-of-hospital cardiac arrest, as defined by the initial rhythm recorded by emergency rescue personnel, has a powerful impact on outcome. The subgroup of patients who are in sustained VT at the time of first contact, although small, has the best outcome. Eighty-eight percent of patients in cardiac arrest related to VT were successfully resuscitated and admitted to the hospital alive, and 67% were ultimately discharged alive. However, this relatively low-risk group represents only 7% to 10% of all cardiac arrests. Because of the inherent time lag between collapse and initial recordings, it is likely that many more cardiac arrests begin as rapid sustained VT and degenerate into VF before the arrival of rescue personnel.

Patients with a bradyarrhythmia or with asystole or PEA at initial contact have the worst prognosis; only 9% of such patients in the Miami study were admitted to the hospital alive, and none were discharged. In a later experience, some improvement in outcome was noted, although the improvement was limited to patients in whom the initial bradyarrhythmia recorded was an idioventricular rhythm that responded promptly to chronotropic agents in the field. In a large prospective observational in-hospital study of cardiac arrests in children and adults, children had a higher probability of asystole or PEA as the initial documented rhythm but had a better overall survival rate because they had better outcomes of interventions for these rhythms than adults did.¹⁴⁸ Overall survival after PEA appears to be better in recent years,¹⁴⁹ but it is not clear whether this applies to asystole.

Bradyarrhythmias also have adverse prognostic implications after defibrillation from VF in the field. Patients with a heart rate lower than 60 beats/min after defibrillation, regardless of the specific bradyarrhythmic mechanism, had a poor prognosis, with 95% of such patients dying before hospitalization or in the hospital. The outcome in the group of patients in whom VF is the initial rhythm recorded is intermediate between the outcomes associated with sustained VT and with bradyarrhythmia and asystole. Of such patients, 40% were resuscitated successfully and admitted to the hospital alive, and 23% were ultimately discharged alive. Later data indicate improvement in outcome. The proportion of each of the electrophysiologic mechanisms responsible for cardiac arrest varied among the earlier reports, with VF ranging from 65% to more than 90% of the study populations and bradyarrhythmia and asystole ranging from 10% to 30%. However,

in reports from densely populated metropolitan areas, the ratios of tachyarrhythmic to bradyarrhythmic or pulseless activity events were reversed, and outcomes were far worse.¹³⁹

Initial Assessment and Basic Life Support

Activities at initial contact with the unconscious victim include diagnostic maneuvers and basic cardiopulmonary support interventions. The first action must be confirmation that collapse is or is suspected of being a cardiac arrest. A few seconds of evaluation for response to voice, observation for respiratory movements and skin color, and simultaneous palpation of major arteries for the presence or absence of a pulse yields sufficient information to determine whether a life-threatening incident is in progress. Once a life-threatening incident has been suspected or confirmed, contact with an available emergency medical rescue system (911) for out-of-hospital settings or a "code" team in the hospital should be an immediate priority.

The absence of a carotid or femoral pulse detected by a medical professional, particularly if it is confirmed by the absence of an audible heartbeat, is a primary diagnostic criterion. For lay responders, the pulse check is no longer recommended.¹²⁴ Skin color may be pale or intensely cyanotic. Absence of respiratory effort or the presence of only agonal respiratory effort in conjunction with an absent pulse is diagnostic of cardiac arrest; however, respiratory effort can persist for 1 minute or longer after onset of the arrest. In contrast, absence of respiratory effort or the presence of severe stridor with persistence of a pulse suggests a primary respiratory arrest that will lead to cardiac arrest in a short time. In the latter circumstance, initial efforts should include exploration of the oropharynx in search for a foreign body and performance of the Heimlich maneuver, particularly if the incident occurs in a setting in which aspiration is likely (e.g., restaurant death or café coronary).

Chest Thump

When the diagnosis of a pulseless collapse is established, a blow to the chest (precordial thump, "thumpversion") may be attempted by a properly trained rescuer. It has been recommended that it be reserved as an advanced life support activity.¹⁴⁰ Its use has been supported on the basis of a prospective study involving 5000 patients. Precordial thumps successfully reverted apparent VF in 5 events, VT in 11, asystole in 2, and undefined cardiovascular collapse in 2 others in which the electrical mechanism was unknown. In no case was conversion of VT to VF observed. Because the latter is the only major concern about the precordial thump technique and electrical activity can be initiated by mechanical stimulation in an asystolic heart, the technique is considered optional for responding to a pulseless cardiac arrest in the absence of monitoring when a defibrillator is not immediately available. It should not be used unmonitored in a patient with a rapid tachycardia without complete loss of consciousness. The thumpversion technique involves one or two blows delivered firmly to the junction of the middle and lower thirds of the sternum from a height of 8 to 10 inches. The effort should be abandoned if a spontaneous pulse does not develop immediately and the patient does not begin breathing. Another mechanical method, which requires that the patient still be conscious, is so-called cough-induced cardiac compression. It is a conscious act of forceful coughing by the patient that may support forward flow by cyclical increases in intrathoracic pressure during VF or may cause conversion of sustained VT. Available data supporting its successful use are limited, and it is not considered an alternative to conventional techniques.

Basic Life Support—The Initial Steps in Cardiopulmonary Resuscitation

The goal of this activity is to maintain viability of the central nervous system, heart, and other vital organs until definitive return of spontaneous circulation can be achieved. Basic life support encompasses both the initial responses outlined earlier and their natural flow into establishing perfusion and ventilation. This range of activities can be carried out not only by professional and paraprofessional personnel but also by trained emergency technicians and laypeople. Time is

crucial, so there should be minimal delay between diagnosis and preparatory effort in the initial response and institution of basic life support. This principle has measurable impact for out-of-hospital and in-hospital cardiac arrest. The survival rate to discharge for in-hospital cardiac arrest, considering all causes and mechanisms, was reported to be 33% when CPR was initiated within the first minute versus 14% when the time was longer than 1 minute (odds ratio [OR], 3.06).¹²⁷ When VF was the initial rhythm, the corresponding figures were 50% and 32%, respectively. In the out-of-hospital setting, if only one witness is present, notification of emergency personnel (calling 911) is the only activity that should precede basic life support. The previous sequence of the “ABC” of basic life support—airway, breathing, compression—has been changed to “CAB”—compression, airway, breathing—based on the recognition that compression alone is the better strategy¹⁵⁰ because it minimizes interruptions in perfusion and avoids excessive ventilation.^{124,140}

Circulation. This element of basic life support is intended to maintain blood flow (i.e., circulation) until definitive steps can be taken. The rationale is based on the hypothesis that chest compression allows the heart to maintain an externally driven pump function by sequential emptying and filling of its chambers, with competent valves favoring forward direction of flow. In fact, application of this technique has proved successful when it is used as recommended.¹²⁴ The palm of one hand is placed over the lower half of the sternum and the heel of the other rests on the dorsum of the lower part of the hand. The sternum is then depressed, with the rescuator’s arms straight at the elbows to provide a less tiring and more forceful fulcrum at the junction of the shoulders and back (Fig. e39-4). By use of this technique, sufficient force is applied to depress the sternum at least 2 inches (>5 cm), with abrupt relaxation, and the cycle is carried out at a rate of about 100 compressions/min.¹²⁴

Techniques of CPR based on the hypothesis that increased intrathoracic pressure is the prime mover of blood, rather than cardiac compression itself, have been evaluated, and the guidelines for conventional CPR ventilatory techniques were modified in 2005. For single responders to victims from infancy (excluding newborns) through adulthood and for adults responded to by two rescuers, a compression-ventilation ratio of 30:2 is now recommended.¹²⁴ For two-rescuer CPR in infants and children, the former compression-ventilation ratio of 15:2 is retained. A more recent modification intended to encourage more bystander participation in CPR and to allay concerns about mouth-to-mouth ventilation of unknown victims is the “hands-only” (compression-only) technique.¹⁵¹ This technique is particularly important for untrained or remotely trained bystanders who are not confident in their ability to perform compression-ventilation sequences. The 2005 changes in CPR recommendations, in which the number of successive shocks and pulse checks during initial responses is reduced (see [Defibrillation-Cardioversion](#)), are retained in the 2010 recommendations. This is intended in part to increase the cumulative time of circulatory support during CPR before restoration of a spontaneous pulse.¹⁵²

Concept of Cardiocerebral Resuscitation. This concept, also referred to as minimally interrupted cardiac resuscitation, is based on the hypothesis that the primary benefit of CPR is its pumping action rather than the combination of compression and ventilation. It challenges the general guidelines, which assume a benefit of interrupting compression to provide ventilation and that an initial phase of ventilation before initial defibrillation improves outcomes when response times are longer than 4 or 5 minutes. Cardiocerebral resuscitation emphasizes continuous chest compressions, interrupted primarily for single shocks and evaluation of responses to shocks and deferring and limiting ventilatory and certain pharmacologic actions. Data from studies in Japan¹⁵³ and the United States^{154,155} suggest a neurologically intact survival advantage of the cardiocerebral protocol over conventional CPR based on the 2000 guidelines and 2005 update. For witnessed arrests with documented VF, the study from Japan demonstrated a neurologically intact survival rate advantage of 22% versus 10%. The two recent reports from the United States demonstrated comparable advantages of 39% versus 15% for neurologically intact survival and 28.4% versus 11.9% for survival, respectively. Despite these interesting data, it remains generally agreed that a randomized trial is needed before the minimal interruption concept can replace the current guidelines.

Even though conventional techniques produce measurable carotid artery flow with a record of successful resuscitations, the absence of a pressure gradient across the heart in the presence of an

extrathoracic arteriovenous pressure gradient has led to the concept that it is not cardiac compression per se but rather a pumping action produced by changes in pressure in the entire thoracic cavity that optimizes systemic blood flow during resuscitation. Experimental work in which the chest is compressed during ventilations rather than between them (simultaneous compression-ventilation) has demonstrated better extrathoracic arterial flow. However, increased carotid artery flow does not necessarily equate with improved cerebral perfusion, and the reduction in coronary blood flow caused by elevated intrathoracic pressure with the use of certain techniques may be too high a price for the improved peripheral flow. In addition, a high thoracoabdominal gradient has been demonstrated during experimental simultaneous compression-ventilation, which could divert flow from the brain in the absence of concomitant abdominal binding. On the basis of these observations, new mechanically assisted techniques, including an active decompression phase (i.e., active compression-decompression), have been evaluated for improved circulation during CPR.¹⁵⁶ More clinical studies are needed before their general clinical application can be established.

Airway. Clearing of the airway is a critical step in preparing for successful resuscitation. This process includes tilting the head backward and lifting the chin, in addition to exploring the airway for foreign bodies, including dentures, and removing them. The Heimlich maneuver should be performed if there is reason to suspect that a foreign body is lodged in the oropharynx. This maneuver entails wrapping the arms around the victim from the back and delivering a sharp thrust to the upper part of the abdomen with a closed fist. If it is not possible for the person in attendance to carry out the maneuver because of insufficient physical strength, mechanical dislodgment of the foreign body can sometimes be achieved by abdominal thrusts with the unconscious patient in a supine position. The Heimlich maneuver is not entirely benign; ruptured abdominal viscera in the victim have been reported, as has a case in which the rescuer disrupted his own aortic root and died. If there is strong suspicion that respiratory arrest precipitated cardiac arrest, particularly in the presence of a mechanical airway obstruction, a second precordial thump should be delivered after the airway has been cleared.

Breathing. With the head placed properly and the oropharynx clear, mouth-to-mouth resuscitation can be initiated if no specific rescue equipment is available. To a large extent the procedure used to establish ventilation depends on the site at which the cardiac arrest occurs. Various devices are available, including plastic oropharyngeal airways, esophageal obturators, masked Ambu bags, and endotracheal tubes. Intubation is the preferred procedure, but time should not be sacrificed, even in the in-hospital setting, while awaiting an endotracheal tube or a person trained to insert it quickly and properly. Thus, in the in-hospital setting, temporary support with Ambu bag ventilation is the usual method until endotracheal intubation can be carried out, and in the out-of-hospital setting, mouth-to-mouth resuscitation is used while awaiting emergency rescue personnel. The effect of acquired immunodeficiency syndrome and hepatitis B transmission on attitudes about mouth-to-mouth resuscitation by bystanders and even professional personnel in hospitals is an area of concern, but currently available data assessing risk for infection suggest that it is minimal.¹²⁴ The impact of this concern on attitudes toward and outcomes of resuscitative efforts has not been evaluated.

Early Defibrillation by First Responders. The time from the onset of cardiac arrest to advanced life support influences outcome statistics. Both early neurologic status and survival are better in patients defibrillated by first responders than if one awaits the assistance of more highly trained paramedics. The term *first responder* refers to the person on scene providing the initial resuscitative action and has emerged from minimally trained emergency technicians allowed to carry out defibrillation in conjunction with basic life support to nonconventional responders, such as trained security guards and police, and most recently to laypersons knowledgeable in CPR with access to AEDs. Because the time to defibrillation plays a central role in determining outcome in cardiac arrest caused by VF, the development and deployment of AEDs (see [Chapter 36](#)) in the community hold promise for progress in the future. This technology is potentially applicable to a number of different strategic models, each with its own benefits and limitations (Fig. 39-15 and see Fig. e39-2). Previous studies that focused on young competitive athletes have led health authorities in some countries to dismiss the implementation of accessible AEDs in public venues because of a perceived lack of cost-effectiveness. This

FIGURE e39-4 External chest compression. **Left**, Locating the correct hand position on the lower half of the sternum. **Right**, Proper position of the rescuer, with the shoulders directly over the victim's sternum and the elbows locked. (From National Academy of Sciences, National Research Council: *Standards and guidelines for cardiopulmonary resuscitation [CPR] and emergency cardiac care [ECC]*. JAMA 255:2906, 1986.)

study demonstrated a considerable increase in sports-related deaths when recreational athletes of a wider age range are considered. Because CPR (OR, 3.73; $P < 0.0001$) and cardiac defibrillation (OR, 3.71; $P < 0.0001$) were the strongest independent predictors of survival to hospital discharge (15.7%), survival from sudden death in recreational sports could be improved significantly by increased public education in CPR responses and availability of public AEDs.

Among the strategies that have yielded various levels of identifiable survival benefit to date are deployment in police vehicles, airliners and airports,^{157,158} casinos,¹⁵⁹ and more general community-based sites.^{160,161} Police AED deployment data have been inconsistent in various studies, possibly because of appropriateness for various types of communities and the specific deployment strategies used, but data suggest that it is beneficial in large metropolitan areas (Fig. e39-5). Initial airline data were similarly uncertain, but a more recent report on data from a large airline with a well-organized system has suggested benefit (Fig. e39-6). Similar encouraging results have been reported with the deployment of AEDs in the Chicago airport system. Finally, the special circumstance of casinos, in which continuous television monitoring alerts security officers to medical problems immediately, has yielded impressive survival rates (Fig. 39-16). For more general community sites, defined as true public access, a large study has suggested a twofold benefit.¹⁶⁰ However, there appears to be a great deal of variability in efficiency on the basis of expected event rates at different types of community sites, and deployment strategies have been suggested on the basis of projected event rates at various locations.^{160,161} Deployment in schools, accompanied by comprehensive response planning, is associated with relatively low event rates but good outcomes.¹⁶² A study of the deployment of AEDs in the homes of patients who recently had myocardial infarctions and were not candidates for implantable defibrillators did not demonstrate benefit.¹⁶³ Because the home is the most common site of cardiac arrest and survival rates are lower than those in public sites, additional strategies for both AEDs and other technologies should be tested. Additional data have also demonstrated limited efficacy of home-based AEDs⁷; further research on effective strategies is needed because most community-based cardiac arrests occur in the home.

As is the case with any medical device,¹⁶⁴ malfunctions of AEDs may occur infrequently because of design or manufacturing defects¹⁶⁵ or failure to adhere to manufacturers' recommendations for replacement of batteries and leads. It is an obligation of those responsible for maintaining AEDs to remain cognizant of FDA safety alerts and recalls and the shelf-lives of batteries and leads.

Advanced Life Support

This next step in the resuscitative sequence is designed to achieve stable return of spontaneous circulation and hemodynamic stabilization.^{124,140} Implementation of advanced life support is not intended to suggest an abrupt cessation of basic life support activities but rather a merging and transition from one level of activity to the next. In the past, advanced life support required judgments and technical skills that removed it from the realm of activity of lay bystanders and even emergency medical technicians, instead limiting these activities to specifically trained paramedical personnel, nurses, and physicians. With further education of emergency technicians, most community-based CPR programs now permit them to carry out advanced life support activities. However, some studies suggest that the addition of advanced life support to an otherwise optimized out-of-hospital response system (i.e., bystander CPR and early defibrillation) does not improve statistics for neurologically intact survival.¹⁶⁶ In this regard, the development and testing of AEDs that have the ability to sense and analyze cardiac electrical activity and to prompt the user

FIGURE 39-15 Various deployment strategies for nonconventional responders with access to AEDs. For each example, the type of rescuer and the advantages and limitations of each strategy are provided. It is unlikely that any single strategy will dominate; rather, there will be a cumulative benefit from the additive effect of multiple approaches. (From Myerburg RJ: Sudden cardiac death: Exploring the limits of our knowledge. *J Cardiovasc Electrophysiol* 12:369, 2001.)

Casino AED Project: Witnessed Response Times and Outcomes

FIGURE 39-16 Results of AED deployment in the controlled environment of casinos. Because the onset of cardiac arrest can frequently be witnessed, short intervals from the onset of collapse to CPR and AED shocks were achieved. Response times were reduced by more than 50% in comparison to the standard emergency medical system (EMS). For those found in VT/VF, the survival rate was better than expected from other community-based systems and approached 60% for VT/VF with a witnessed onset. When response time was less than 3 minutes, the survival rate after VT/VF was higher than 70%. (Modified from Valenzuela TD, Roe DJ, Nichol G, et al: Outcomes of rapid defibrillation by security officers after cardiac arrest in casinos. *N Engl J Med* 343:1206, 2000.)

to deliver definitive electrical intervention provide a role for rapid defibrillation by less highly trained rescue personnel (i.e., police, ambulance drivers) and even untrained or minimally trained lay bystanders.

The general goals of advanced life support are to restore cardiac rhythm to one that is hemodynamically effective, to optimize ventilation, and to maintain and support the restored circulation. Thus, during advanced life support, the patient's cardiac rhythm is promptly cardioverted or defibrillated as the first priority if appropriate equipment is immediately available. A short period of closed-chest cardiac compression immediately before defibrillation enhances the probability of survival, especially if circulation has been absent for 4 to 5 or more minutes.^{139,143} After the initial attempt to restore a hemodynamically effective rhythm, the patient is intubated and oxygenated, if needed, and the heart is paced if bradyarrhythmia or asystole occurs. An intravenous line is established to deliver medications.

FIGURE e39-5 Rhythms at initial contact and survival statistics from the Miami-Dade County, Fla., police AED project. Shockable rhythms were observed in just less than 40% of cardiac arrest victims in both the police AED program and the standard emergency medical system (EMS) historical control data. Those with shockable rhythms had improved survival to hospital discharge, but the improvement was small when both shockable and nonshockable rhythms were included in the data analyzed. (Modified from Myerburg RJ, Fenster J, Velez M, et al: Impact of community-wide police car deployment of automated external defibrillators on out-of-hospital cardiac arrest. *Circulation* 106:1058, 2002.)

FIGURE e39-6 Data on outcomes after deployment of AEDs by a major airline demonstrated that approximately 44% of the cardiac arrests were associated with a documented VT/VF mechanism and 40% of these victims survived. There were no survivors among the 56% of the victims who had nonshockable rhythms. The cumulative survival rate for the program was 17%. (A, Modified from Page RL, Joglar JA, Kowal RC, et al: Use of automated external defibrillators by a U.S. airline. *N Engl J Med* 343:1210, 2000.)

After intubation, the goal of ventilation is to reverse the hypoxemia and not merely to achieve high alveolar oxygen pressure (PO_2). Thus oxygen rather than room air should be used to ventilate the patient; if possible, arterial PO_2 should be monitored. Respiratory support in the hospital by means of an endotracheal tube and Ambu bag—or facemasks in the out-of-hospital setting—are generally used.

Successful return of spontaneous circulation after in-hospital cardiac arrest is associated with a shorter median duration of resuscitation than is the case in nonsurvivors (12 minutes, interquartile range [IQR] of 6 to 21, versus 20 minutes, IQR of 14 to 30). Nonetheless, hospitals that habitually ran the longest maximum code runs (the median value in the longest quartile was 25 versus 16) generated a higher likelihood of return of spontaneous circulation and survival to discharge.¹⁶⁷ This observation supports longer attempts at resuscitation in patients without “do-not-resuscitate” instructions and/or futile medical status.

Defibrillation-Cardioversion

Rapid conversion to an effective cardiac electrical mechanism is a key step in successful resuscitation (**Fig. 39-17**). Delay should be minimal, even when conditions for CPR are optimal. When VF or VT that is pulseless and/or accompanied by loss of consciousness is recognized on a monitor or by telemetry, defibrillation should be carried out immediately. An initial shock of 360 J should be delivered by monophasic devices and 120 to 200 J by biphasic devices, with the energy depending on the recommendations for the individual biphasic devices. Energies delivered through AEDs are generally preprogrammed and vary among the devices available. Failure of the initial shock to provide an effective rhythm is a poor prognostic sign. The 2010 updated guidelines^{124,140} recommend that failure of a single adequate shock to restore a pulse should be followed by continued CPR and a second shock delivered after five cycles of CPR. This supersedes the previous strategy of three successive shocks before resuming CPR. The intent is to maximize circulatory time by chest compressions until a pulse has been restored. If cardiac arrest still persists, the patient is intubated and intravenous access achieved. Epinephrine is administered and followed by repeated defibrillation attempts at 360 J (monophasic) or 200 J or higher (biphasic). Epinephrine may be repeated at 3- to 5-minute intervals with a defibrillator shock in between,^{124,140} but studies of the value of high-dose versus standard-dose epinephrine have been inconsistent with regard to short-term added benefit (i.e., return of spontaneous circulation); there does not appear to be any long-term benefit (i.e., survival to hospital discharge) with higher doses.¹⁶⁸ Vasopressin is an effective alternative to epinephrine.

Simultaneously, the rescuer should focus on ventilation to correct the chemistry of the blood and render the heart more likely to reestablish a stable rhythm, such as improved oxygenation, reversal of acidosis, and improvement of the underlying electrophysiologic condition. Although adequate oxygenation of the blood is crucial in immediate management of the metabolic acidosis of cardiac arrest, additional correction can be achieved, if necessary, by the intravenous administration of sodium bicarbonate. Sodium bicarbonate is recommended for circumstances of known or suspected preexisting bicarbonate-responsive causes of acidosis, certain drug overdoses,

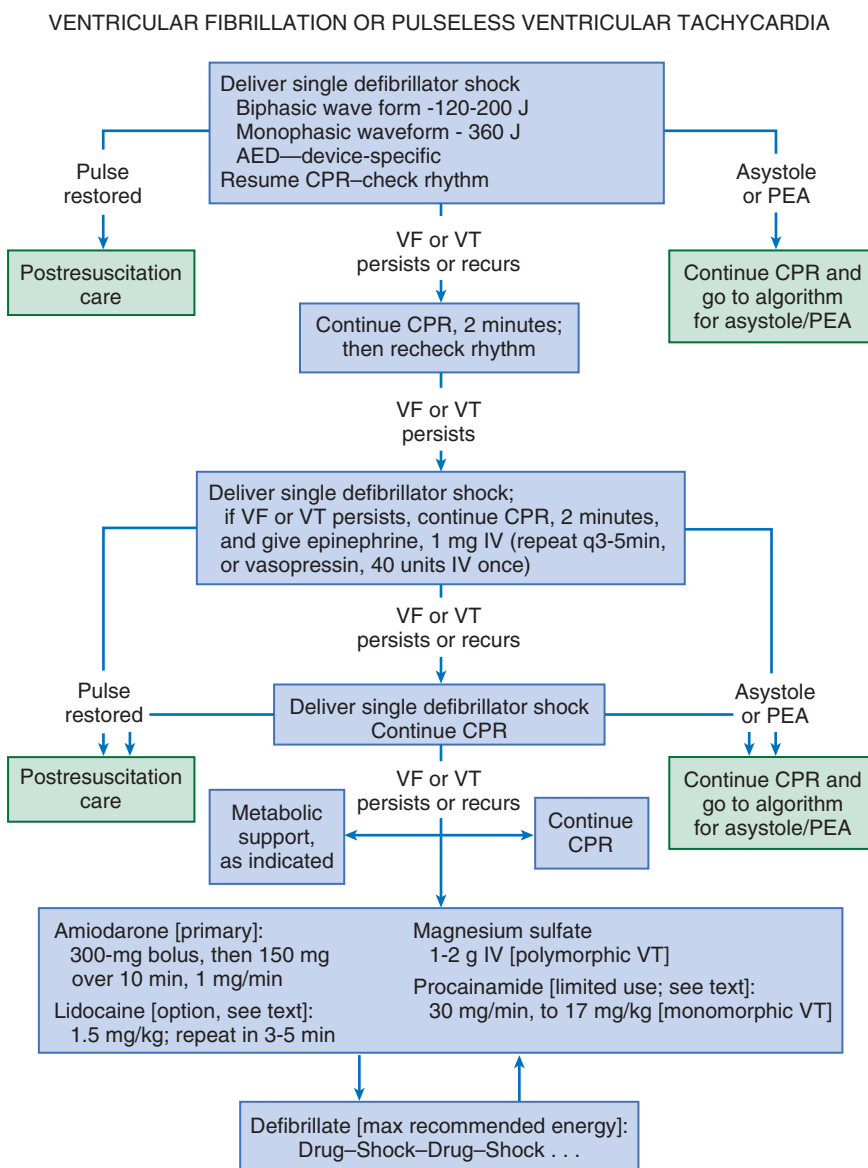

FIGURE 39-17 Advanced life support for VF and pulseless VT. If initial defibrillation fails, the patient should be intubated and intravenous access established immediately while CPR is continued. Epinephrine, 1 mg intravenously, should be administered and may be repeated several times with additional defibrillation attempts at 360 J. If conversion is still unsuccessful, epinephrine may be administered again, although it is unlikely that higher doses will provide any further benefit. Sodium bicarbonate should be administered at this time only if the patient is known to be hyperkalemic, and intravenous antiarrhythmic drugs should be tried (see text). Additional attempts to defibrillate should follow the administration of each drug attempted. Concomitant with all steps, continuation of CPR is paramount. (Modified from 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science. *Circulation* 122[Suppl 3]:S640, 2010.)

and prolonged resuscitation runs.¹⁴⁰ A more general role of bicarbonate during cardiac arrest has been questioned, but in any circumstance, much less sodium bicarbonate than was previously recommended is adequate for the treatment of acidosis in this setting. Excessive quantities can be deleterious. Although some investigators have questioned the use of sodium bicarbonate because the risk for alkalosis, hyponatremia, and hyperosmolality may outweigh its benefits, the circumstances cited may benefit from the administration of sodium bicarbonate while CPR is being carried out. Up to 50% of the dose may be repeated every 10 to 15 minutes during the course of CPR. When possible, arterial pH, PO_2 , and PCO_2 should be monitored during the resuscitation.

Pharmacotherapy

Pharmacotherapy
For patients who continue to have persistent or recurrent VT or VF despite direct-current cardioversion after epinephrine, electrical

stability of the heart may be achieved by the intravenous administration of antiarrhythmic agents (see Chapter 35) during continued resuscitative efforts (see Fig. 39-17). Intravenous amiodarone has emerged as the initial treatment of choice.¹²⁴ Bolus therapy is followed by a maintenance dose during the next 18 hours and for several days, as necessary, depending on the stability of the rhythm.

A bolus of lidocaine may be given intravenously and the dose repeated in 2 minutes for patients in whom amiodarone is unsuccessful and possibly for those who have an acute transmural myocardial infarction as the triggering mechanism for the cardiac arrest. Intravenous procainamide is rarely used in this setting any longer, but it may be tried for persisting, hemodynamically stable arrhythmias.

For patients in whom acute hyperkalemia is the triggering event for resistant VF or for those who have hypocalcemia or are toxic from Ca^{2+} entry-blocking drugs, 10% calcium gluconate may be helpful.¹⁴⁰ Calcium should not be used routinely during resuscitation, even though ionized calcium levels may be low during resuscitation from cardiac arrest. Some resistant forms of polymorphic VT or torsades de pointes, rapid monomorphic VT or ventricular flutter (rate $\geq 260/\text{min}$), or resistant VF may respond to intravenous beta blocker therapy or intravenous magnesium sulfate. For patients with acute ventricular arrhythmias or VT storm associated with long-QT syndrome, intravenous magnesium sulfate is often an effective antiarrhythmic, even if it has no effect on QT duration.

Bradyarrhythmic and Asystolic Arrest; Pulseless Electrical Activity

The approach to patients with bradyarrhythmic or asystolic arrest or with PEA differs from the approach to those with a tachyarrhythmic event (Fig. 39-18).^{124,140} When this form of cardiac arrest is recognized, effort should focus first on establishing control of cardiorespiratory status (i.e., continue CPR, intubate, and establish intravenous access), reconfirming the rhythm (in two leads if possible), and finally taking action that favors the emergence of a stable spontaneous rhythm or attempt to pace the heart. Possible reversible causes, particularly for bradyarrhythmia and asystole, should be considered and excluded (or treated) promptly. Such causes include hypovolemia, hypoxia, cardiac tamponade, tension pneumothorax, preexisting acidosis, drug overdose, hypothermia, and hyperkalemia. Epinephrine is commonly used in an attempt to elicit spontaneous electrical activity or to increase the rate of a bradycardia. It has had only limited success, as has intravenous isoproterenol infusions in doses of up to 15 to 20 $\mu\text{g}/\text{min}$. In the absence of an intravenous line, epinephrine, 1 mg (10 mL of a 1:10,000 solution), may be given by the intracardiac or intraosseous route, but there is danger of coronary or myocardial laceration with the former. The added value of high-dose epinephrine is unclear,¹⁶⁸ as in the case of resistant VF. Atropine is no longer considered of value for PEA or asystole,¹²⁴ although it may be of benefit for other bradyarrhythmic mechanisms. Sodium bicarbonate, 1 mEq/kg, may be tried for known or strongly suspected preexisting hyperkalemia or bicarbonate-responsive acidosis.

Pacing of a bradyarrhythmic or asystolic heart has been limited in the past by the unavailability of personnel capable of carrying out such procedures at the scene of cardiac arrest. With the development of more effective external pacing systems, the role of pacing and its influence on outcome must now be reevaluated. Unfortunately, all data to date have suggested that asystolic patients continue to have a very poor prognosis despite new techniques.

The published standards for CPR and emergency cardiac care^{124,140} include a series of teaching algorithms to be used as guides to appropriate care. Figures 39-17 and 39-18 provide the algorithms for VF and pulseless VT, asystole (or cardiac standstill), and PEA. These general guides are not to be interpreted as inclusive of all possible approaches or contingencies. The special circumstance of CPR in pregnant women requires additional attention to the effects of drugs on the

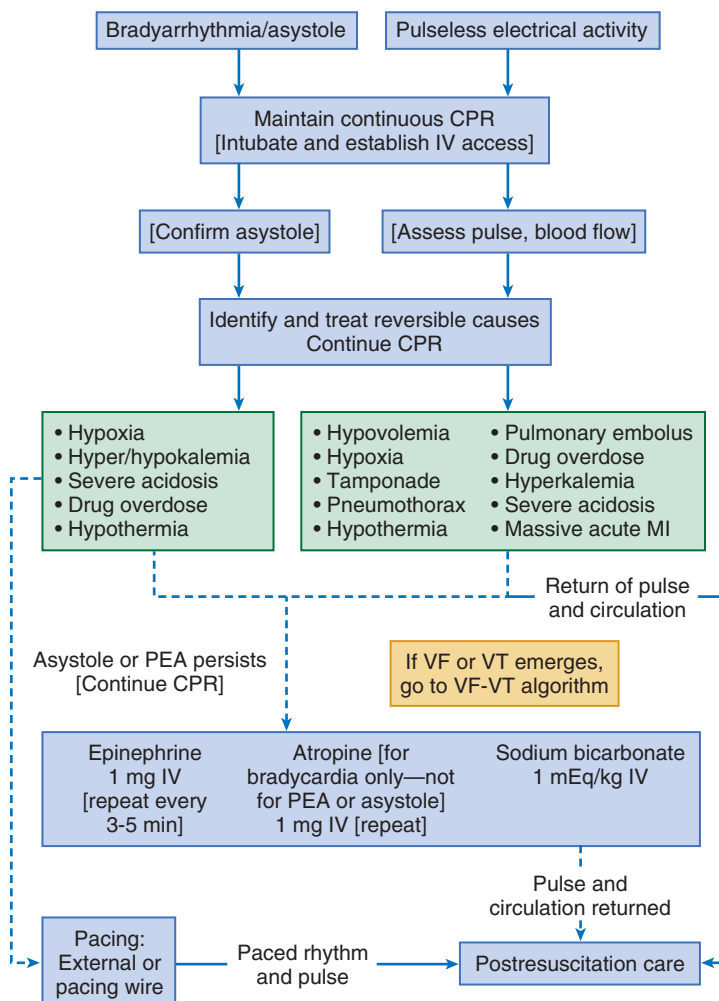

FIGURE 39-18 Advanced cardiac life support for patients with bradyarrhythmic-asystolic arrest and PEA. A patient in any of these states should have CPR continued and be intubated, with intravenous access established, before pharmacologic treatment. The initial activity is to confirm persisting asystole or attempt to assess blood flow in patients thought to have PEA. An immediate attempt should be made to identify and treat reversible or treatable causes of these forms of cardiac arrest. Epinephrine is generally administered first, and atropine or bicarbonate, or both, may be administered subsequently. An attempt to pace the heart with an external device or an intracardiac pacing catheter is advisable although not usually successful, except for certain reversible bradyarrhythmias. MI = myocardial infarction. (From 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science. *Circulation* 122[Suppl 3]:S640, 2010.)

gravid uterus and the fetus, the mechanical and physiologic influences of pregnancy on the efficacy of CPR, and the risk for complications such as a ruptured uterus and lacerated liver.

Stabilization of Cardiac Rhythm after Initial Return of Spontaneous Circulation

If frequent PVCs and runs of nonsustained VT persist after restoration of a sinus mechanism, continuous infusion of an effective antiarrhythmic drug is used. Intravenous amiodarone is the preferred agent. Lidocaine is an option for arrhythmias caused by acute ischemic events, and intravenous procainamide may be considered if the others fail. On occasion, continuous infusion of propranolol or esmolol is used, sometimes in conjunction with magnesium sulfate, especially for recurrent episodes of polymorphic VT or VT storm unresponsive to amiodarone.

Catecholamines are used for cardiac arrest not only in an attempt to achieve better electrical stability (e.g., conversion from fine to coarse VF or increasing the rate of spontaneous contraction during bradyarrhythmias) but also for their inotropic and peripheral vascular effects. Epinephrine is the first choice among the catecholamines for use in cardiac arrest because it increases myocardial contractility,

elevates perfusion pressure, may convert electromechanical dissociation to electromechanical coupling, and improves the chances for successful defibrillation. Because of its adverse effects on renal and mesenteric flow, norepinephrine is a less desirable agent despite its inotropic effects. When the chronotropic effect of epinephrine is undesirable, dopamine or dobutamine is preferable to norepinephrine for inotropic effect. Isoproterenol may be used for the treatment of primary or postdefibrillation bradycardia when heart rate control is the primary goal of therapy intended to improve cardiac output. Calcium chloride is sometimes used in patients with PEA that persists after the administration of catecholamines. The efficacy of this intervention is uncertain. Stimulation of alpha adrenoceptors may be important during definitive resuscitative efforts. For example, the alpha adrenoceptor-stimulating effects of epinephrine and higher dosages of dopamine, which elevate aortic diastolic pressure by peripheral vasoconstriction with increased cerebral and myocardial flow, have been reemphasized.

Post-Cardiac Arrest Care and Post-Cardiac Arrest Syndrome

After return of spontaneous or stable assisted circulation, regardless of the initial electrical mechanism, focus shifts to the diagnostic and therapeutic elements of post-cardiac arrest syndrome.¹⁶⁹ This recently developed field of pathophysiology and clinical intervention emerged from the recognition that the various elements of injury following cardiac arrest should be organized into a multidisciplinary continuum. The four elements of post-cardiac arrest syndrome include brain injury, myocardial dysfunction, systemic ischemia/reperfusion responses, and control of persistent precipitating factors. The therapeutic goal is to achieve and maintain stable electrical, hemodynamic, and central nervous system status. Each has been developed into a complex algorithm described in detail in a scientific consensus statement.¹⁶⁹

For successfully resuscitated cardiac arrest victims, whether the event occurred in or out of the hospital, post-cardiac arrest care includes admission to an intensive care unit and continuous monitoring for a minimum of 48 to 72 hours. Some elements of post-cardiac arrest syndrome are common to all resuscitated patients, but the prognosis and certain details of management are specific for the clinical setting in which the cardiac arrest occurred. The major management categories include (1) primary cardiac arrest in patients with acute myocardial infarction; (2) secondary cardiac arrest in patients with acute myocardial infarction; (3) cardiac arrest associated with non-cardiac-related diseases, drug effects, or electrolyte disorders; and (4) survival after out-of-hospital cardiac arrest.

Primary Cardiac Arrest in Patients with Acute Myocardial Infarction

VF in patients with acute myocardial infarction free of concomitant hemodynamic complications (i.e., primary VF; [see Chapter 52](#)) is now less common in hospitalized patients than the 15% to 20% incidence noted before the availability of cardiac care units. The events that do occur are almost always reverted successfully by prompt interventions in properly equipped emergency departments or cardiac care units. If ventricular arrhythmias persist after successful resuscitation, a lidocaine infusion is used. Antiarrhythmic support is generally discontinued after 24 hours if sustained arrhythmias do not recur ([see Chapter 35](#)). The occurrence of VF during the early phase of acute myocardial infarction (i.e., first 24 to 48 hours) does not identify long-term risk and is not an indication for long-term antiarrhythmic or device therapy. Pulseless VT producing the clinical picture of cardiac arrest in acute myocardial infarction is treated similarly; its intermediate- and long-term implications are the same as those of VF. Cardiac arrest caused by bradyarrhythmias or asystole in acute *inferior* wall myocardial infarction, in the absence of primary hemodynamic deterioration, is uncommon and may respond to atropine or pacing. The prognosis is good, with no special long-term care

required in most cases. Persistent symptomatic bradyarrhythmias requiring permanent pacemakers rarely occur in such patients. In contrast, bradyarrhythmic cardiac arrest associated with large *anterior* wall infarctions (and AV or intraventricular block) has a poor prognosis.

Secondary Cardiac Arrest in Patients with Acute Myocardial Infarction

This condition is defined as cardiac arrest occurring in association with or as a result of hemodynamic or mechanical dysfunction. The immediate mortality of patients in this setting ranges from 59% to 89%, depending on the severity of the hemodynamic abnormalities and size of the myocardial infarction. Resuscitative efforts commonly fail in such patients, and when they are successful, post-cardiac arrest management is often difficult. When secondary cardiac arrest occurs by the mechanisms of VT or VF, aggressive hemodynamic or anti-ischemic measures may help achieve rhythm stability. Intravenous amiodarone has emerged as the antiarrhythmic therapy of choice. Lidocaine may also be tried if the mechanism appears to be ischemic but is less likely to be successful in this setting than in primary VF. The success of interventions and prevention of recurrent cardiac arrest are closely related to the success in managing the patient's hemodynamic status. The incidence of cardiac arrest caused by bradyarrhythmias or asystole or by PEA is higher in the secondary form of cardiac arrest in patients with acute myocardial infarction. Such patients usually have large myocardial infarctions and major hemodynamic abnormalities and may be acidotic and hypoxic. Even with aggressive therapy, the prognosis after asystolic arrest in such patients is poor, and they are resuscitated only rarely from PEA. All patients in circulatory failure at the onset of arrest are in a high-risk category, with only a 2% survival rate in hypotensive patients noted in one study.

Cardiac Arrest among In-Hospital Patients with Noncardiac Abnormalities

These patients fall into two major categories: (1) those with life-limiting diseases, such as malignant neoplasms, sepsis, organ failure, end-stage pulmonary disease, and advanced central nervous system disease, and (2) those with acute toxic or proarrhythmic states that are potentially reversible. In the former category, the ratio of tachyarrhythmic to bradyarrhythmic cardiac arrest is low, and the prognosis for survival of cardiac arrest is poor. Although the data may be somewhat skewed by the practice of assigning "do-not-resuscitate" orders to patients with end-stage disease, the data available for attempted resuscitations show a poor outcome. Only 7% of cancer patients, 3% of renal failure patients, and no patients with sepsis or acute central nervous system disease were successfully resuscitated and discharged from the hospital. For the few successfully resuscitated patients in these categories, postarrest management is dictated by the underlying precipitating factors.

Most antiarrhythmic drugs ([see Chapter 35](#)), a number of drugs used for noncardiac purposes, and electrolyte disturbances can precipitate potentially lethal arrhythmias and cardiac arrest. Class IA and class III antiarrhythmic drugs can cause proarrhythmic responses by lengthening the QT interval and generating torsades de pointes. Class IC drugs rarely cause torsades de pointes but result in excess risk for SCD in patients with recent myocardial infarction, possibly by interacting with transient ischemia. Among other categories of drugs, the phenothiazines, tricyclic antidepressants, lithium, terfenadine interacting with ketoconazole (or other blockers of enzymes in the hepatic P-450 system), pentamidine, cocaine, erythromycin, and cardiovascular drugs that are not antiarrhythmics (such as lidoflazine) are recognized causes. Beyond these, a broad array of pharmacologic and pathophysiologic-metabolic causes have been reported. Hypokalemia, hypomagnesemia, and perhaps hypocalcemia are the electrolyte disturbances most closely associated with cardiac arrest. Acidosis and hypoxia can potentiate the vulnerability associated with electrolyte disturbances. Proarrhythmic effects are often forewarned by prolongation of the QT interval, although this electrocardiographic change is not always present.

Impending or manifest cardiac arrest caused by torsades de pointes is managed by the intravenous administration of magnesium, pacing, or treatment with isoproterenol and removal of the offending agent. When QT prolongation is the basis, magnesium may effectively control the arrhythmia without shortening the QT interval. Class IC drugs may cause a rapid, sinusoidal VT pattern, especially in patients with poor left ventricular function. This VT has a tendency to recur repetitively after cardioversion until the drug has begun to clear, and it has been controlled by propranolol in some patients. When the patient's condition can be stabilized until the offending factor is removed (e.g., proarrhythmic drugs) or corrected (e.g., electrolyte imbalances, hypothermia), the prognosis is excellent. Recognition of torsades de pointes (see Chapter 37) and identification of its risk by prolongation of the QT interval in association with the offending agent are helpful in managing these patients.

Post-Cardiac Arrest Care in Survivors of Out-of-Hospital Cardiac Arrest

The initial management of survivors of out-of-hospital cardiac arrest centers on stabilizing cardiac electrical status, supporting hemodynamics, and providing supportive care for reversal of any organ damage that has occurred as a consequence of the cardiac arrest. The in-hospital risk for recurrent cardiac arrest is relatively low, and arrhythmias account for only 10% of in-hospital deaths after successful out-of-hospital resuscitation. However, the mortality rate during the index hospitalization is 50%, thus indicating that nonarrhythmic mortality dominates the mechanisms of early postresuscitation deaths (30% hemodynamic, 60% central nervous system related). Antiarrhythmic therapy, usually intravenous amiodarone, is used in an attempt to prevent recurrent cardiac arrest in patients who demonstrate recurrent arrhythmia during the first 48 hours of postarrest hospitalization. Patients who have preexisting or new AV or intraventricular conduction disturbances are at particularly high risk for recurrent cardiac arrest. The routine use of temporary pacemakers has been evaluated in such patients but has not been found to be helpful for prevention of early recurrent cardiac arrest. Invasive techniques for hemodynamic monitoring are used in patients whose condition is unstable but are not used routinely in those whose condition is stable on admission.

Anoxic encephalopathy is a strong predictor of in-hospital death. A suggested addition to the management of this condition is induction of mild hypothermia to reduce metabolic demands and cerebral edema.^{128,129} When this strategy is applied promptly to a postarrest survivor who remains unconscious on hospital admission, there is a modest but measurable survival benefit. During the later convalescent period, continued attention to central nervous system status, including physical rehabilitation, is of primary importance for an optimal outcome. Respiratory support by conventional methods is used as necessary. Management of other organ system injury (e.g., renal, hepatic), as well as early recognition and treatment of infectious complications, also contributes to ultimate survival.

Long-Term Management of Survivors of Out-of-Hospital Cardiac Arrest

When a survivor of out-of-hospital cardiac arrest has awakened and achieved electrical and hemodynamic stability, usually within a few days if it is to occur at all, decisions must be made about the nature and extent of the workup required to establish a long-term management strategy. The goals of the workup are to identify the specific causative and triggering factors of the cardiac arrest, to clarify the functional status of the patient's cardiovascular system, and to establish long-term therapeutic strategies. The extent of the workup is largely dictated by the degree of central nervous system recovery and the factors already known to have contributed to the cardiac arrest. Patients who have limited return of central nervous system function do not usually undergo extensive workups, and patients whose cardiac arrests were triggered by an acute transmural myocardial infarction have workups similar to those for other patients with acute myocardial infarction (see Chapter 52).

Survivors of out-of-hospital cardiac arrest not associated with acute myocardial infarction who have good return of neurologic function appear to have a long-term survival probability commensurate with their age, sex, and extent of disease when they are treated according to existing guidelines.^{132,134,170-172} These patients should undergo diagnostic workups to define the cause of the cardiac arrest and to tailor long-term therapy, the latter targeted to the underlying disease and strategies for prevention of recurrent cardiac arrest or SCD. The workup includes cardiac catheterization with coronary angiography if coronary atherosclerosis is known or considered to be the possible cause of the event, evaluation of the functional significance of coronary lesions by stress imaging techniques if indicated, determination of functional and hemodynamic status, and assessment of whether the life-threatening arrhythmic event was caused by a transient risk associated with acute myocardial infarction or whether there is persisting risk based on clinical characteristics.

General Care

The general management of survivors of cardiac arrest is determined by the specific cause and the underlying pathophysiologic process. For patients with ischemic heart disease (see Chapters 53 and 54), who constitute approximately 80% of cardiac arrest victims, interventions to prevent myocardial ischemia, optimization of therapy for left ventricular dysfunction, and attention to general medical status are all addressed. Although limited data suggest that revascularization procedures may improve the recurrence rate and total mortality rates after survival from out-of-hospital cardiac arrest, no properly controlled prospective studies have validated this impression for bypass surgery or percutaneous interventions. Moreover, a randomized trial of prophylactic implantable defibrillators versus usual therapy in patients with low ejection fractions undergoing coronary bypass surgery in the absence of a history of cardiac arrest or other life-threatening arrhythmia or arrhythmia markers (the Coronary Artery Bypass Graft [CABG] Patch trial) revealed no mortality benefit of implantable defibrillators after revascularization.⁷² The indications for revascularization after cardiac arrest are limited to those who have a generally accepted indication for angioplasty or surgery, including (but not limited to) a documented ischemic mechanism of the cardiac arrest.

Although no data from placebo-controlled trials are available to define a benefit of various anti-ischemic strategies (including beta blockers or other medical anti-ischemic therapy) for long-term management after out-of-hospital cardiac arrest, medical, catheter interventional, or surgical anti-ischemic therapy, rather than antiarrhythmic drug therapy, is generally considered the primary approach to long-term management of the subgroup of prehospital cardiac arrest survivors in whom transient myocardial ischemia was the inciting factor. Moreover, in an uncontrolled observation comparing cardiac arrest survivors who had ever received beta blockers after the index event with those who had not received that class of drug, a significant improvement in long-term outcome was observed in those who received beta blockers. Further evaluation of the specific role of revascularization procedures and anti-ischemic medical therapy after out-of-hospital cardiac arrest is needed.

Long-term management of the consequences of left ventricular dysfunction by conventional means, such as digitalis preparations and chronic diuretic use, has been evaluated in several studies. Data from MRFIT (Multiple Risk Factor Intervention Trial) suggested a higher mortality rate in the special intervention group, presumably related to diuretic use and potassium depletion, and other data regarding the relationship between potassium depletion and arrhythmias have focused attention on the routine use of such drugs. Although the facts are currently far from conclusive, it is advisable that diuretic use be accompanied by careful monitoring of electrolyte levels.

The various pharmacologic strategies (e.g., angiotensin-converting enzyme inhibitors, carvedilol and other beta-adrenergic-blocking agents, and spironolactone) that have been shown to provide a clinical and mortality benefit in patients with left ventricular dysfunction, with or without heart failure, provide an SCD benefit in conjunction with a total mortality benefit. The extent to which cardiac arrest

survivors achieve a specific SCD benefit is uncertain, although some primary prevention trials have suggested that such benefit does occur.

PREVENTION OF CARDIAC ARREST AND SUDDEN CARDIAC DEATH

Prevention of SCD can be classified into five clinical subgroup categories: (1) prevention of recurrent events in survivors of cardiac arrest or pulseless VT (secondary prevention) or other symptomatic

tachycardias considered life-threatening (Table 39-7); (2) prevention of an initial event in patients at high risk because of advanced heart disease with low ejection fractions and other markers of risk (primary prevention) (Table 39-8); (3) primary prevention in patients with less advanced common or uncommon structural heart diseases; (4) primary prevention in patients with structurally normal hearts, subtle or minor structural abnormalities, or genetically based molecular disorders that establish risk for ventricular arrhythmias (Table 39-9); and (5) primary prevention in the general population. The last category includes the substantial proportion of SCDs that

occur as a first cardiac event in victims previously free of known disease (see earlier).

Four antiarrhythmic strategies, which are not mutually exclusive, may be considered for patients at risk for cardiac arrest: implantable defibrillators, antiarrhythmic drugs, catheter ablation, and antiarrhythmic surgery. In addition to these specific antiarrhythmic strategies, therapies for other medical and cardiovascular conditions are integral to managing patients at risk for SCD.

The choice of a therapy, or combinations of therapies, is based on estimation of risk determined by evaluation of the individual patient by various risk-profiling techniques, coupled with available efficacy and safety data.

Methods to Estimate Risk for Sudden Cardiac Death

General Medical and Cardiovascular Risk Markers

The presence and severity of acquired medical disorders (such as coronary atherosclerosis and associated myocardial ischemia or magnetic resonance imaging–defined scar patterns, left ventricular dysfunction and ventricular volume, and heart failure), and general medical conditions (such as hypertension, diabetes, dyslipidemias, chronic renal failure, and cigarette smoking), are integral to estimation of risk for SCD. Although lacking the specificity of individual SCD risk prediction attributable to some of the specific arrhythmia markers, they provide general indicators of risk and data supporting the benefit of therapies, such as beta blockers, angiotensin-converting enzyme inhibitors and receptor blockers, and statins, in appropriate subgroups of patients. In patients with known or suspected coronary heart disease or nonischemic cardiomyopathy, other noninvasive markers of risk are being explored, including measures reflecting autonomic function, QT interval stability, and genetic influences on risk for SCD (see [Risk Factors for Sudden Cardiac Death](#)). The potential importance of proper timing and combining of risk markers has been explored.² One study suggested greater risk predictive power for post-myocardial infarction adverse events when markers were evaluated after 8 weeks, as opposed to closer to the index event.¹⁷³ In another study, optimized medical and interventional therapy at the time of an acute myocardial infarction was associated with a dramatically reduced risk for SCD during long-term follow-up.¹⁷⁴

Ambulatory Monitoring. The development of reliable methods of analysis of ambulatory recordings has led some investigators to study the usefulness of such recordings to profile risk for sustained tachyarrhythmic events and to measure suppressibility of ambient arrhythmias as a specific and individualized means of evaluating drug therapy for prevention of SCD (see [Chapter 34](#)). The latter is now obsolete as a primary approach in cardiac arrest survivors, but ambulatory monitoring is still used for profiling the risk for development of life-threatening sustained arrhythmias in individuals with certain forms of structural or electrophysiologic disease who are considered to be at high risk. For example, the strategies in MADIT (Multicenter Automatic Defibrillator Implantation Trial) and MUSTT (Multicenter Unsustained Tachycardia Trial) used identification of nonsustained VT in post-myocardial infarction patients with other risk markers for early mortality.⁷² Although the ambient arrhythmias were not a target for therapy in the design of the studies, they established the usefulness of this technique for identification of risk. Similarly, ambulatory recordings, particularly in patients with symptoms, are used as an aid to risk profiling in disorders such as hypertrophic cardiomyopathy, long-QT syndrome, and right ventricular dysplasia and in patients with dilated cardiomyopathy or heart failure. In patients with possible risk for SCD based on low-frequency symptomatic events, such as near-syncope or syncope, with or without a perception of repetitive palpitations or tachycardias, an implantable loop recorder for recording and retrieval of transient events may provide risk-profiling benefit.

Programmed Electrical Stimulation. Despite a large, albeit somewhat conflicting data base on the role of electrophysiologic testing for risk profiling, particularly in patients with advanced heart disease, its use is currently more limited than in the past. In primary prevention trials such as MADIT and MUSTT, programmed electrical stimulations studies were used to profile risk and suggested large benefits.⁷² MADIT II, which enrolled patients with lower ejection

fractions than did MADIT or MUSTT and did not use programmed stimulation or other arrhythmia markers, also demonstrated a survival benefit of ICD therapy. The extent to which MADIT II differs from MADIT and MUSTT and the question of whether the electrophysiologic testing criteria in the latter are useful have yet to be fully resolved. However, a follow-up study of patients in MADIT II suggested that cumulative ICD discharge rates were equivalent in those who had inducible and noninducible ventricular tachyarrhythmias, although inducibility was associated with a higher incidence of VT and noninducibility with VF.¹⁷⁵

The secondary prevention trials of cardiac arrest survivors did not seek to determine whether routine electrophysiologic testing offered predictive value,⁷² and it is no longer necessary, particularly if ICD therapy is available to the patient. Most previous studies had demonstrated limitations because of the relatively small fraction of cardiac arrest survivors (an average of less than 50% on the basis of multiple studies) who had inducible arrhythmias. Under conditions in which a potentially reversible trigger for cardiac arrest can be identified and perhaps in some cardiac arrest survivors in whom transient ischemia was the initiating mechanism and the ejection fraction is higher than 40%, there might be a persistent limited role for such testing as a guide to therapy.

For patients with symptomatic arrhythmia or those considered to be at potentially high risk, programmed stimulation is still used. Inducibility of sustained or hemodynamically unstable arrhythmias, initiated with an appropriate protocol, is considered positive and predictive. However, the implications of induced nonsustained forms of VT are more controversial. Although it has been suggested that induction of nonsustained ventricular rhythms may indicate risk, it is generally considered nonspecific in the absence of structural heart disease or when an aggressive protocol is used. The reliability of noninducibility to predict absence of risk is also questioned.¹⁷⁵ Despite conflicting opinions, it is generally accepted now that survivors of cardiac arrest without clearly identifiable transient and treatable causes remain at high risk, regardless of their inducibility status. Some out-of-hospital cardiac arrests can clearly be demonstrated to result from transient ischemia, and this subgroup appears to achieve benefit from anti-ischemic therapy.¹³⁴

Strategies to Reduce Risk for Sudden Cardiac Death

Antiarrhythmic Drugs

Historically, the earliest approach to management of risk for out-of-hospital cardiac arrest and VT with hemodynamic compromise was the use of membrane-active antiarrhythmic agents. This approach was based initially on the assumption that a high frequency of ambient ventricular arrhythmias constituted a triggering mechanism for potentially lethal arrhythmias and that their suppression by antiarrhythmic drugs was protective. It was also assumed that electrophysiologic instability of the myocardium that predisposed to potentially lethal arrhythmias could be modified by these drugs and that suppression of inducibility of VT or VF during programmed electrical stimulation studies reflected this effect. Suppression of ambient arrhythmias was demonstrated by the empiric use of amiodarone, beta-adrenergic–blocking agents, or membrane-active antiarrhythmic drugs, but scientifically valid demonstration of a survival benefit was lacking. The observation that post-cardiac arrest survivors who had been treated with class I antiarrhythmic drugs had a worse outcome than did those who were not treated challenged the concept of benefit. That skepticism was definitively reinforced by the results of CAST, which demonstrated that certain class I antiarrhythmic drugs are neutral or harmful. In contrast, beta blocker therapy might have some benefit in such patients, and amiodarone might also be effective for some patients,⁷² although it did not perform better than the control group in the heart failure patients studied in SCD-HeFT (Sudden Cardiac Death–Heart Failure Trial). Affirmative data have defined the superiority of ICD therapy for most survivors of tachyarrhythmic cardiac arrest.

In summary, ambient arrhythmia suppression and empiric antiarrhythmic drug therapy enjoyed a short period of popularity as a strategy for reduction of risk in VT/VF survivors but in time yielded to the apparently greater benefits of amiodarone, as well as perhaps

beta blockers, prescribed empirically. The combination of amiodarone and beta blocker therapy in post-myocardial infarction patients has been suggested as a strategy that provides greater benefit than either drug alone from subgroup analysis of EMIAT (European Myocardial Infarct Amiodarone Trial) and CAMIAT (Canadian Amiodarone Myocardial Infarction Trial), and another study reinforced the benefit of beta blockers for the specific prevention of SCD in unselected post-myocardial infarction patients.⁴¹ A study of the cardiovascular effects of the amiodarone analogue dronedarone suggested an arrhythmic death survival benefit in patients with atrial fibrillation,¹⁷⁶ but this observation was based on a secondary analysis of a small number of events and should not be considered conclusive without more data. Moreover, additional data suggest that the drug may have adverse effects in patients with heart failure or persistent/permanent atrial fibrillation.^{177,178} Whether this translates specifically to risk for SCD remains unknown. The combination of amiodarone and beta blocker therapy in post-myocardial infarction patients has been suggested as a strategy that provides greater benefit than either drug alone does from subgroup analysis of post-myocardial infarction amiodarone studies, and another study reinforced the benefit of beta blockers for the specific prevention of SCD in unselected post-myocardial infarction patients.³⁵

Therapy Guided by Programmed Electrical Stimulation. The second major antiarrhythmic strategy was based on suppression of inducibility of sustained ventricular arrhythmias, considered to be a marker of risk during electrophysiologic testing. The use of programmed electrical stimulation to identify benefit on the basis of suppression of inducibility by an antiarrhythmic drug gained popularity for evaluation of long-term therapy in survivors of out-of-hospital cardiac arrest. It had evolved as the preferred method of management despite concerns about the sensitivity and specificity of the various pacing protocols and the extent to which myocardial status at the time of the programmed electrical stimulation study reflects that present at the time of the clinical cardiac arrest. Nonetheless, most studies have demonstrated limitations based on observations that a relatively small fraction of cardiac arrest survivors (an average of fewer than 50% on the basis of multiple studies) had inducible arrhythmias.

Drug suppression of inducibility during electrophysiologic testing as an endpoint for secondary prevention of SCD or primary prevention in high-risk post-myocardial infarction patients has yielded to the benefits of ICD therapy in most subgroups, with a few exceptions in the primary prevention categories. It still has use, however, for risk profiling in a number of clinical circumstances.^{175,179} Use of suppression of nonsustained arrhythmias as an endpoint of therapy is not considered valid.

Surgical Intervention Strategies. The previously popular antiarrhythmic surgical techniques now have limited applications. Intraoperative map-guided cryoablation may be used for patients who have inducible, hemodynamically stable, sustained monomorphic VT during electrophysiologic testing and ventricular and coronary artery anatomy amenable to catheter ablation. However, it has little applicability to survivors of out-of-hospital cardiac arrest because the type of arrhythmia favoring this surgical approach is infrequently observed in cardiac arrest survivors. It can be used as adjunctive therapy for ICD recipients whose arrhythmia burden requires frequent shocks. In addition, coronary revascularization procedures have a clearly defined role for cardiac arrest survivors in whom an ischemic mechanism was responsible for the event and suitable surgical anatomy is present.

Catheter Ablation Therapy. The use of catheter ablation techniques to

treat ventricular tachyarrhythmias has been most successful for benign focal tachycardias that originate in the right ventricle or left side of the interventricular septum (see Chapter 35) and for some reentrant VTs. With rare exceptions, catheter ablation techniques are not used for the treatment of higher risk ventricular tachyarrhythmias or for definitive therapy in patients at risk for progression of the arrhythmic substrate. For VT caused by bundle branch reentrant mechanisms, which occur in cardiomyopathies, as well as in other structural cardiac disorders, ablation of the right bundle branch to interrupt the reentrant cycle has been successful. However, this has limited applicability to the large number of patients with structural heart disease who are at risk for SCD or those who have survived a cardiac arrest. Nonetheless, catheter ablation is an appropriate adjunctive treatment strategy for patients with ICDs who are having multiple tachyarrhythmic events. A study suggested a potential preventive benefit of VT substrate ablation in survivors of cardiac arrest equivalents (VF, hemodynamically limiting VT, or syncope with VT inducibility) with a history of myocardial infarction.¹⁸⁰ Presently, this benefit is limited to reducing the number of patients receiving ICD therapy (33% with an ICD alone versus 12% with an ICD plus ablation; hazard ratio, 0.35; $P = 0.007$), and further studies are needed to determine whether it has an expanded role.

Implantable Defibrillators. Development of the ICD added a new dimension to the management of patients at high risk for cardiac arrest (see Chapter 36). After the initial reports of small case series of very high-risk patients in the early 1980s, a number of observational studies confirmed that ICDs can achieve rates of sudden death consistently less than 5% at 1 year and total death rates in the 10% to 20% range in populations at high risk for mortality, as predicted by mortality surrogates such as historical controls or time to the first appropriate shock.⁷² However, determination of the mortality benefit of ICDs remained uncertain and was debated for many years (Fig. 39-19). More than 16 years elapsed between the first clinical use of an implanted defibrillator and publication of the first major randomized clinical trial comparing implantable defibrillator therapy with antiarrhythmic drug therapy.⁷² During that period, reports had documented the ability of ICDs to revert potentially fatal arrhythmias but could not identify a valid relative or absolute mortality benefit because of confounding factors, such as competing risks for sudden and nonsudden death and determination of whether appropriate shocks represented

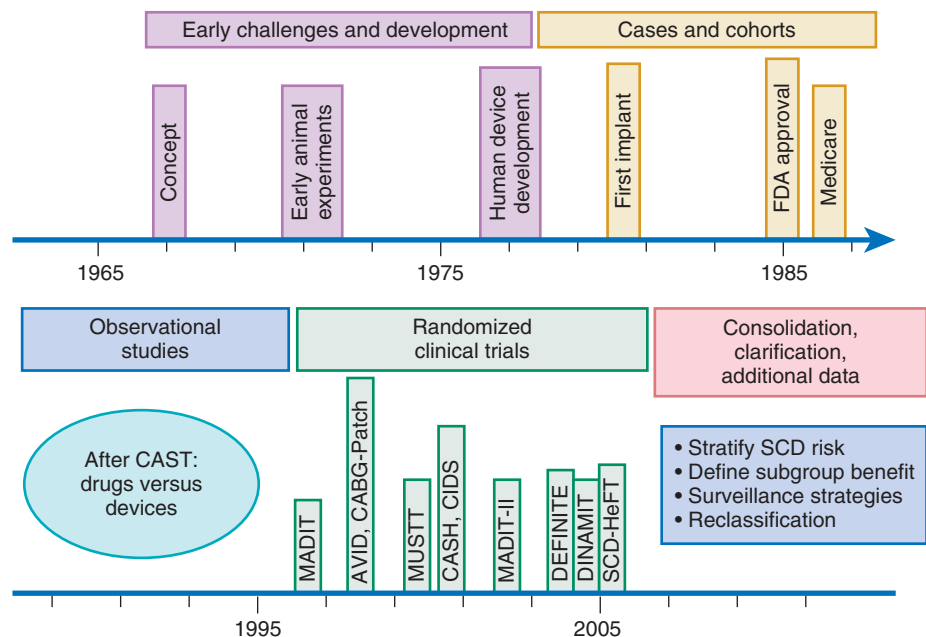

FIGURE 39-19 The concept of an ICD originated in the late 1960s, and development of the technology and proof of concept leading to the first clinical implant extended to 1980. From 1980 until late 1996, data supporting the benefit of ICDs were largely observational or based on small high-risk cohorts or case-control studies. All the major trials for both primary and secondary indications were published during an interval of 10 years between late 1996 and early 2005. Additional studies since then have aided in interpretation of the outcomes from the clinical trials, but there remains a need for consolidation and clarification and for additional data to better define the efficiency of therapy and targeted selection of individual candidates who have a high likelihood of benefit. (Modified from Myerburg RJ, Reddy V, Castellanos A: Indications for implantable cardioverter-defibrillators based on evidence and judgment. *J Am Clin Cardiol* 54:747, 2009.)

the interruption of an event that would have been fatal. Despite these limitations, ICD therapy continued to increase its relative position among other forms of therapy for survivors of out-of-hospital cardiac arrest and, to a lesser extent, for those considered to be at high risk for a primary cardiac arrest on the basis of specific clinical markers.

With publication of the results of MADIT, information on the relative benefit of defibrillators over antiarrhythmic drug therapy (largely amiodarone) for primary prevention of SCD in a very high-risk population based on controlled randomized trial data finally became available. The outcome demonstrated a 59% reduction in the relative risk for total mortality at 2 years of follow-up (54% cumulative) and a 19% reduction in the absolute risk of dying at 2 years of follow-up. It was followed during a period of less than 10 years by a series of randomized trial reports evaluating ICD therapy for primary and secondary prevention of SCD in patients with previous myocardial infarction, previous cardiac arrests, and heart failure.

Although these studies documented the ability of implantable devices to revert potentially fatal arrhythmias and subsequently showed a relative benefit over amiodarone in some groups of patients, the absence of placebo-controlled trials still prevents quantitation of the true magnitude of any mortality benefit because of the inability of positive-controlled trials to identify the absolute benefit of an intervention. Despite these limitations, an ICD is now the preferred therapy for survivors of cardiac arrest at risk for recurrences and for

primary prevention in patients in a number of high-risk categories. Major questions still unanswered include the relative benefit of amiodarone versus defibrillators in lower risk subgroups of survivors of out-of-hospital cardiac arrest, the role of beta blockers, and the role of anti-ischemic surgical and medical therapy as definitive approaches.

A much larger issue—and one that has not yet been defined—is the use of implantable defibrillators for primary prevention of cardiac arrest in patients thought to be at intermediate levels of risk. Studies of cost-effectiveness, in addition to medical efficacy, are needed.

Application of Therapeutic Strategies to Specific Groups of Patients

Secondary Prevention of Sudden Cardiac Death after Survival of Cardiac Arrest

As populations of cardiac arrest survivors began to accumulate from community-based emergency rescue activities, therapeutic strategies intended to improve long-term survival emerged as a mandate for clinical investigators. The problem that affects all long-term strategies for cardiac arrest survivors, however, is the lack of a reliable concurrent natural history denominator against which to compare the results of interventions. This lack is a consequence of ethical concerns about withholding therapy in a placebo-controlled study model

for patients at high risk of dying, in conjunction with the confounding influence of general therapies used in such patients that may also improve survival. Early approaches to long-term therapy centered on the use of antiarrhythmic drug therapy, largely guided by the results of electrophysiologic testing or the empiric use of antiarrhythmic drugs, particularly amiodarone. Various observational and positive-controlled studies had suggested that suppression of inducible ventricular arrhythmias yielded a better outcome than did failure of suppression and that amiodarone was better than class I antiarrhythmic drugs. The first adequately powered secondary prevention trial of ICDs versus antiarrhythmic drugs was published in 1997. This study, the AVID trial, demonstrated a 27% reduction in the relative risk for total mortality at 2 years of follow-up, with an absolute risk reduction of 7% (Fig. 39-20).⁷² It was followed shortly thereafter by reports of two other studies, CIDS (Canadian Implantable Defibrillator Study) and CASH (Cardiac Arrest Study Hamburg), both limited by the power of the enrollment numbers but suggesting trends toward similar benefits (see Table 39-7). As a consequence of the secondary prevention trials, ICDs have emerged as the preferred therapy for survivors of out-of-hospital cardiac arrest or hemodynamically important VT. A subgroup analysis of AVID has suggested that the advantage of ICDs over antiarrhythmic drugs might be limited to patients with ejection fractions lower than 35%. Because it is a retrospective analysis, the observation calls for confirmation in a controlled trial.

Although only one of the secondary prevention trials (AVID) demonstrated a statistically significant survival benefit of an ICD over antiarrhythmic therapy, usually amiodarone, the other two showed trends toward a survival benefit, supported by a meta-analysis.¹⁸¹ Despite this limitation, ICD therapy has emerged as the preferred therapy, regardless of the ejection fraction, for survivors without identifiable and correctable transient causes of cardiac arrest. It has largely supplanted anatomically based antiarrhythmic surgery and pharmacologic antiarrhythmic approaches for secondary prevention.

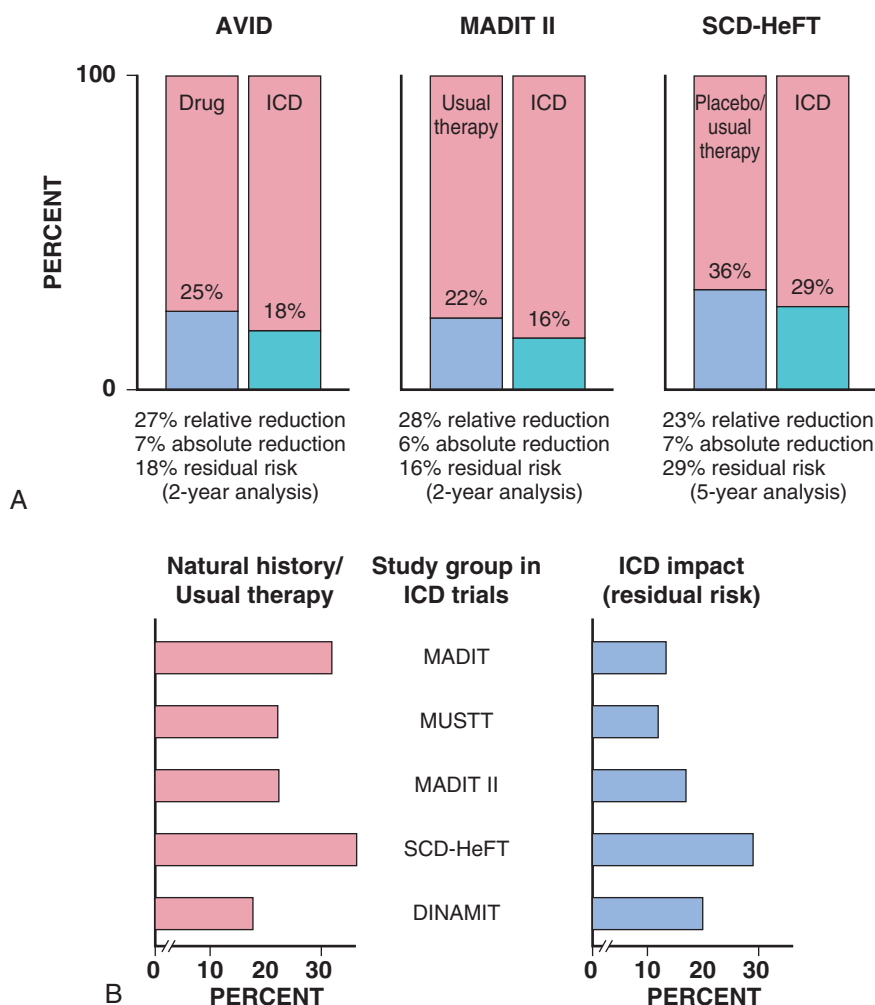

FIGURE 39-20 **A**, Relative and absolute benefits of ICDs in three ICD trials: a secondary prevention study (AVID) trial, a primary prevention trial (MADIT II), and a heart failure sudden death trial (SCD-HeFT); see text for definitions and trial descriptions. Relative risk reductions indicate proportional differences in outcomes between test and control populations, absolute reductions indicate proportional benefits for individuals, and residual risks indicate mortality remaining after accounting for ICD benefits. **B**, Residual risk after accounting for ICD-associated survival benefit in five major primary prevention ICD clinical trials. (**A**, Modified from Myerburg RJ, Mitrani R, Interian A Jr, Castellanos A: Interpretation of outcomes of antiarrhythmic clinical trials: Design features and population impact. *Circulation* 97:1514, 1998.)

Primary Prevention of Sudden Cardiac Death in Patients with Advanced Heart Disease

After the disturbing outcome of CAST and suggestions of a lack of efficacy or adverse effects of the class I antiarrhythmic drugs in general when used for primary or secondary prevention of SCD, interest shifted to the use of amiodarone and implantable defibrillators. Two major trials of amiodarone in post-myocardial infarction patients, EMIAT and CAMIAT, one of which required ejection fractions lower than 40%, demonstrated no total mortality benefit, even though both trials demonstrated antiarrhythmic benefit, expressed as a reduction in arrhythmic deaths or resuscitated VF. Subgroup analyses have suggested that the concomitant use of beta blockers does confer a mortality benefit.

In parallel with the amiodarone trials, the first randomized controlled trial comparing antiarrhythmic therapy (primarily amiodarone) with ICD therapy (MADIT) was carried out (see Table 39-8). The randomly assigned patients had ejection fractions lower than 35%, nonsustained VT during ambulatory recording, and inducible VT that was not suppressible by procainamide. This very high-risk group demonstrated a 54% reduction in total mortality with ICD therapy versus drug therapy, primarily amiodarone. At the same time, a trial comparing ICD implantation with no specific therapies for arrhythmias in patients with ejection fractions lower than 36% who were undergoing coronary bypass surgery (CABG Patch trial) demonstrated no benefit of defibrillators on total mortality. The only marker for arrhythmic risk required for entry into the study was a positive signal-averaged electrocardiogram. A third trial, MUSTT,⁷² was a complex study designed to determine whether electrophysiologically guided therapy would lead to an improved outcome in patients with ambient nonsustained VT, inducible VT, history of previous myocardial infarction, and ejection fraction lower than 40%. The results demonstrated that although a statistically significant beneficial effect on total mortality was achieved by guiding therapy according to the results of electrophysiologic testing, when compared with patients with inducible tachycardia who did not receive therapy, the subgroup of patients who received ICDs because they failed to respond to drug therapy accounted for all the benefit. Mortality was 24% in ICD-treated patients at 5 years of follow-up versus 55% in those receiving electrophysiologically guided drug therapy and 48% in those randomly assigned to no therapy. MADIT II was next among the post-myocardial infarction primary prevention trials reported. In this study, ICD therapy provided a mortality benefit over conventional therapy in patients with previous myocardial infarction and ejection fractions lower than 30%, with a relative risk reduction of 28% and an absolute risk reduction of 6% (22% versus 16%) at 2 years (see Fig. 39-20). During long-term follow-up, a constant annualized risk of approximately 8.5% was estimated in survivors, with the most powerful risk predictors being age older than 65 years, class III or IV heart failure, diabetes, non-sinus rhythm, and elevated blood urea nitrogen levels.¹⁸²

MADIT and MADIT II had set entry requirements of longer than 3 weeks and longer than 1 month after the qualifying infarction, but the actual enrollment in these studies and MUSTT was considerably longer on average. Because both old and recent²¹ data suggested higher risk for SCD early after myocardial infarctions, DINAMIT (Defibrillator in Acute Myocardial Infarction Trial) was designed to evaluate any possible benefit of ICD implantation early after a myocardial infarction in patients with ejection fractions of 35% or lower⁸³ and other markers of risk. DINAMIT demonstrated no survival benefit attributable to early implantation of ICDs in patients randomly assigned at 6 to 40 days after myocardial infarction (mean, 18 days) despite reduced arrhythmic mortality. There was also an unexplained increase in nonarrhythmic mortality over conventional therapy that needs to be explored in future studies. The absence of early ICD benefit in light of early risk for SCD has led some to call for further studies on this question. The post-myocardial infarction primary prevention studies cited above were all reported between 1996 and 2005 and had been designed and executed beginning in the early 1990s and extending to 2004. More recent data suggest that optimized

therapy during and after myocardial infarction, with “optimized” being defined as revascularization and the use of beta blockers, acetylsalicylic acid, statins, and angiotensin-converting enzyme inhibitors, may beneficially influence risk for SCD during long-term follow-up after the event.¹⁷⁴ In this study, the greatest impact was achieved by revascularization. Even though the ejection fraction was improved in association with these interventions, it was not determined whether risk is improved with ejection fractions equivalent to those in the early ICD trials. However, the population burden of SCD in post-myocardial infarction patients was reduced by these myocardial infarction-related interventions. Another study also suggested that both thrombolytic therapy and percutaneous coronary intervention during acute myocardial infarction and other changes in therapy that have occurred between 1995 and 2010 have improved 30-day mortality.⁴² In a 2009 to 2011 study that enrolled a population of primary prevention candidates similar in profile to those in MADIT II and that was designed to evaluate ICD shocks and mortality based on different ICD therapy strategies,¹⁸⁴ the cumulative mortality at 24 months of follow-up in the conventional programming group was 10% versus 16% in the original MADIT II cohort (1997 to 2001), thus suggesting beneficial influences other than ICDs on outcomes.

A study designed to determine whether patients with nonischemic cardiomyopathy, accompanied by a history of heart failure, ejection fractions of 35% or lower, and PVCs or nonsustained VT, benefit from prophylactic ICD therapy, DEFINITE, was underpowered to achieve statistical significance ($P = 0.08$). However, the reported results demonstrated a strong trend toward benefit, with a 35% reduction in relative risk and a 6% reduction in absolute risk during 2 years of follow-up.¹⁸⁵ Subgroups with prolonged QRS durations, ejection fractions higher than 20%, and class III heart failure performed better than did the overall cohort data. Finally, SCD-HeFT was designed to test the potential benefit of ICDs versus amiodarone and placebo in patients with functional class II or III congestive heart failure and ejection fractions lower than 35%. Nonischemic cardiomyopathy and ischemic cardiomyopathy were almost equally represented, with 85% of the patients with ischemic cardiomyopathy having a history of myocardial infarction. The results of this study demonstrated a 23% reduction in relative risk and a 7% reduction in absolute risk during 5 years¹⁸⁶ (see Fig. 39-20). Amiodarone provided no added benefit over conventional therapy. In contrast to DEFINITE, the class II patients in SCD-HeFT had better outcomes than did the class III patients.

The mortality benefit of ICDs combined with cardiac resynchronization therapy is unclear. Although one study suggested a small mortality benefit in patients with class III and IV heart failure,¹⁸⁷ another study that enrolled class I and II heart failure patients (most of the enrollees being class II) with prolonged QRS durations demonstrated a heart failure hospitalization benefit without a mortality benefit.¹⁸⁸

Primary Prevention in Patients with Less Advanced Common Heart Diseases or Uncommon Diseases.

Primary prevention trials have been designed to enroll populations of patients with advanced heart disease who were estimated to be at very high risk for SCD and total mortality as a consequence of the severity of the underlying disease. Most clinical trials testing the question of the relative efficacy of antiarrhythmic versus ICD therapy have used the ejection fraction as the marker for advanced disease, with the upper limits of qualifying ejection fractions being between 30% and 40% and the majority set at 35%. The mean or median values of those actually enrolled ranged from 21% to 30%,¹⁰¹ and subgroups with ejection fractions higher than 30%, particularly those in the range of 35% to 40%, had lower if any benefit (Fig. 39-21). Moreover, in the secondary prevention trial AVID, a subgroup analysis suggested that there is no survival advantage of ICD therapy over amiodarone in patients with ejection fractions higher than 35%. This observation is important because it raises a question about therapeutic options for both primary and secondary prevention strategies when ejection fractions are higher than 35%. However, because of the absence of controls receiving neither therapy, it is unknown whether the benefit attributable to both therapies is equivalent.

Although the risk for SCD and total mortality is highest in patients with advanced structural heart disease and low ejection fractions, impaired functional capacity, or both, a substantial proportion of the

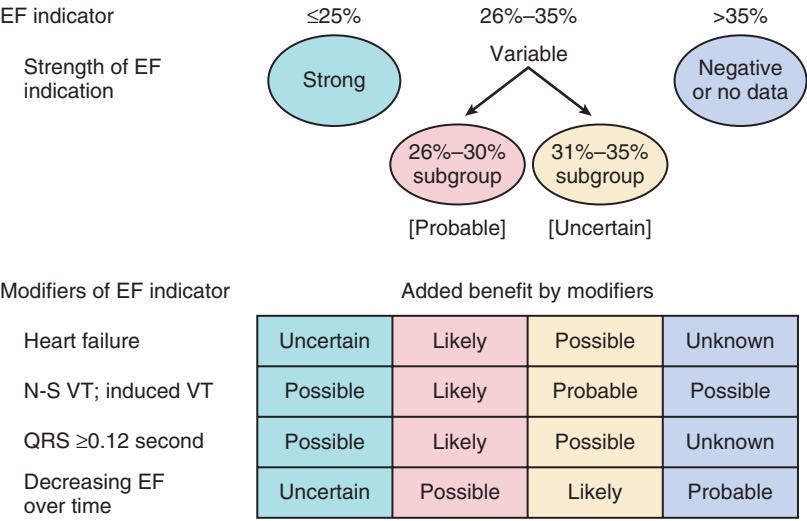

FIGURE 39-21 Modifiers of post-myocardial infarction ejection fraction indicators for ICDs. The strength of ejection fraction (EF) as a primary determinant of indications for an ICD after myocardial infarction varies and is apparently modulated by a number of clinical factors. Although stratified trial data are not available, indications from subgroup analyses suggest general patterns of modification of EF indicators by other influences. In circumstance in which EF alone appears to be a strong indicator (e.g., 20% to 25%), modifiers that have an effect at other levels of EF (e.g., heart failure) may not add further strength of prediction for total mortality. (Modified from Myerburg RJ: Implantable cardioverter-defibrillators after myocardial infarction. *N Engl J Med* 359:2245, 2008.)

total SCD burden occurs in patients with coronary heart disease or the various nonischemic cardiomyopathies with ejection fractions between 35% and 40% and higher. In addition, in patients with heart failure related to various forms of cardiomyopathy, even though the total mortality risk is considerably lower in patients with functional class I or early class II than in those with late class III or class IV status, the probability of a death being sudden is higher in the former group⁴⁴ (see Fig. 39-9). Despite this observation, no data are available to guide therapy for primary prevention of cardiac arrest in such patients.¹¹ This limitation is confounded by the fact that patients in these categories generally have low event rates but cumulatively account for large numbers of SCD (see Fig. 39-2A, B). In addition, certain other structural entities associated with some elevation in risk for SCD in the absence of a severely reduced ejection fraction, such as some patterns of viral myocarditis, hypertrophic cardiomyopathy, right ventricular dysplasia, and sarcoidosis, are managed without the benefit of clinical trials to guide therapeutic decisions (see Table 39-9). Patients with symptomatic ventricular arrhythmias related to structural disorders such as right ventricular dysplasia, in which most of the mortality risk is arrhythmic, are often advised to have an ICD, even in the absence of a previous cardiac arrest or hemodynamically significant VT. Whether antiarrhythmic therapy would be just as effective remains unknown, but the judgment of using defibrillators in patients with a disorder whose fatal expression is primarily arrhythmic carries the strength of logic, often supported by risk profiling based on observational data of clinical markers. Among the entities in which the family history is helpful in defining risk, clinical judgment is made easier in patients with a strong family history of SCD. Specific support for this approach is derived from genetic studies of individuals with hypertrophic cardiomyopathy. In addition, clinical observational data have supported the use of ICDs in high-risk subsets of patients with hypertrophic cardiomyopathy.⁶⁷

Primary Prevention in Patients with Structurally Normal Hearts or Molecular Disorders of Cardiac Electrical Activity. Clinically subtle or unapparent structural disorders and entities with pure electrophysiologic expression, such as the congenital long-QT syndromes, Brugada syndrome, and idiopathic VF, are receiving increasing attention with regard to preventive activities (see Chapter 32). The decision-making process for cardiac arrest or symptomatic VT survivors with long-QT syndrome is similar to that for other entities in that those who have survived a potentially fatal arrhythmia are generally treated with ICDs (Table 39-9). In contrast, individuals who express the electrocardiographic phenotype of long-QT syndrome in the absence of symptomatic arrhythmias are generally treated with beta blocker therapy. Beta blockers are also considered useful for affected family members who have not had an event and

for subgroups of long-QT patients with syncope of undocumented mechanism.⁷² Between these extremes are asymptomatic affected family members of patients with symptomatic long-QT syndrome. Given the complexity of the pathophysiology of potentially fatal arrhythmias in such patients, the threshold for consideration of ICD therapy is decreasing.⁸⁶ Genetic screening may ultimately prove useful for identification of a specific risk, particularly if individual arrhythmic risk is demonstrated to be determined by one or more modifier genes interacting with the defect responsible for an ion channel pore defect.⁶¹ Currently, many such clinical therapeutic decisions remain based on judgment rather than driven by data.¹⁰¹ In this context, a family history of premature SCD in affected relatives appears to be useful in the decision-making process for preventive therapy in this general category of patients.

Among the other molecular arrhythmia syndromes, Brugada syndrome is one for which management strategies remain problematic and debated.^{94,95} An ICD is accepted as the preferred secondary prevention strategy in cardiac arrest survivors and symptomatic affected individuals, even though it is based solely on observational data. However, primary prevention approaches for affected relatives, especially if they are asymptomatic, are unclear. Studies have suggested that syncope associated with electrocardiographic changes suggestive of the disorder at baseline is a marker of risk sufficient to warrant ICD therapy⁹⁴ and that baseline electrocardiographic changes associated with inducibility of ventricular tachyarrhythmias during electrophysiologic testing are also a marker of risk.⁹⁵ Conversely, the absence of

right bundle branch block and ST-T wave changes without provocation suggests lower risk. The appropriate role of electrophysiologic testing remains debated,⁹⁶⁻⁹⁹ impaired in part by the absence of uniform protocols and selection biases based on subgroups studied at various centers. However, a family history of SCD remains an important factor in judgment-based decisions. Similar arguments, but supported by even fewer data, apply to affected family members of patients with right ventricular dysplasia.

Prediction and Primary Prevention in the General Population

Because SCD is frequently the first clinical expression of underlying structural heart disease or occurs in identified patients profiled to be at low risk (see Fig. 39-2B), there has been longstanding interest in risk profiling and therapeutic strategies targeted to primary prevention. To have a major impact on the problem of SCD in the general population, including adolescents and young adults, we need to move beyond the identification of high-risk patients who have specific clinical entities, advanced or subtle, that predict high risk for SCD. Rather, it is necessary to find small subgroups of patients in the general population at specific risk for SCD as a manifestation of underlying heart disease, if and when that disease becomes manifested. As an example, studies that have demonstrated familial clustering of SCD as the first expression of underlying coronary artery disease and thus suggesting a genetic or behavioral predisposition may provide some help for the future.³⁶⁻³⁸ If highly specific markers related to electrophysiologic properties or along multiple points in the cascade of coronary events (see Fig. 39-5) can be found, preventive therapy before the first expression of an underlying disease may have a major effect on the population problem of SCD. Short of that, successes will be limited to community-based intervention and to subgroups that are easier to identify and in whom it is more justifiable to use prophylactic interventional therapy on the basis of population size and magnitude of risk.^{2,72}

Adolescents and young adults, including athletes (see Chapter 79), constitute a group for special consideration. Risk for SCD in these groups is an order of magnitude of 1% of that of the general adult population older than 35 years (see Fig. 39-4).^{10,72} However, most causes of SCD in these populations are not characterized by advanced life-limiting structural heart disease, and therefore surviving cardiac arrest victims can, with appropriate long-term therapy, be expected

TABLE 39-9 Indications for Implantable Cardioverter-Defibrillators in Genetic Disorders Associated with Risk for Sudden Cardiac Death

DIAGNOSIS	ICD INDICATION	PRIMARY SOURCE OF DATA	RISK INDICATORS	GUIDELINES	
				Classification	Evidence
HCM	Secondary SCA protection	Registries, cohorts	Previous SCA, pulseless VT Sustained VT, unexplained syncope	Class I Class IIa	Level B Level C
	Primary SCA protection	Registries, cohorts	Left ventricular thickness >30 mm, high left ventricular outflow gradient, family history of SCD, N-S VT, blunted blood pressure response to exercise	Class IIa	Level C
ARVD/RVCM	Secondary SCA protection	Registry, case series	Previous SCA, sustained VT Unexplained syncope	Class I Class IIa	Level B, C Level C
	Primary SCA protection	Registry, case series	Induced VT, ambient N-S VT, extensive disease	Class IIa	Level C
Congenital LQT	Secondary SCA protection	Registry, cohorts	Previous SCA, symptomatic VT	Class I	Level B
	Primary SCA protection	Registry, cohorts	VT or syncope while taking a beta blocker, QTc >500 msec, family history of premature SCA (?)	Class IIa, IIb	Level B
Familial SQT	Secondary SCA protection	Small case series	Previous SCA, "idiopathic" VF	Class I	Level C
	Primary SCA protection	Small case series	Unknown; family history of SCD (?)	Class IIb, III	Level C
Brugada syndrome	Secondary SCA protection	Case cohorts	Previous SCA, pulseless VT	Class I	Level B
	Primary SCA protection	Case cohorts	Symptomatic VT, unexplained syncope, family history of premature SCA with type I electrocardiographic pattern	Class IIa	Level C
CPVT/F	Secondary SCA protection	Small case series	Previous SCA, pulseless VT	Class I	Level C
	Primary SCA protection	Small case series	Syncope or VT while taking beta blockers, family history of premature SCA (?)	Class IIa	Level C

ARVD/RVCM = arrhythmogenic right ventricular dysplasia/cardiomyopathy; CPVT/F = catecholaminergic polymorphic ventricular tachycardia/"idiopathic" ventricular fibrillation; HCM = hypertrophic cardiomyopathy; LQT = long-QT syndrome; N-S = nonsustained; PVT = polymorphic ventricular tachycardia; SQT = short-QT syndrome; VA = ventricular arrhythmia; (?) = uncertain.

Guideline classifications and levels of evidence are derived from an amalgamation of narrative and tabular statements in two recent guidelines documents,^{170,171} with variations in the documents adjudicated by the authors. Definitions are the standard usages provided in guidelines documents.

From Myerburg RJ, Reddy V, Castellanos A: Indications for implantable cardioverter-defibrillators based on evidence and judgment. *J Am Coll Cardiol* 54:747-763, 2009.

to have significant extensions of life. Because most deaths are arrhythmic, the ability to identify individuals at risk in advance of a life-threatening arrhythmic event offers more long-term impact than in older populations. For both the general young population and athletes, identification of individuals at risk may lead to prevention of events triggered by physical activity. One study has demonstrated a reduction in SCDs in athletes with the use of widespread electrocardiographic screening.¹⁸⁹ In the United States, strategies for screening of adolescents, young adults, and athletes to identify entities that create risk have largely been limited to medical and family histories and physical examination.¹⁹⁰ The European¹⁹¹ and the International Olympic Committee recommendations¹⁹² add electrocardiographic screening for athletes, which continues to be debated in the United States^{193,194} despite data indicating both feasibility^{195,196} and suggestions of cost-effectiveness.¹⁹⁷ Electrocardiographic screening of the general adolescent population, including athletes, can identify many of those at potential risk because of congenital long-QT syndrome, hypertrophic cardiomyopathy, right ventricular dysplasia, and Brugada syndrome. Although electrocardiographic screening in the adolescent and athletic subgroups is imperfect and usually accompanied by depolarization and repolarization patterns that may be difficult to interpret, this strategy can lead to further testing in appropriate individuals. Echocardiography has also been suggested as a screening method, but it is more expensive and less cost-efficient and does not recognize conditions such as long-QT syndrome and Brugada syndrome.

Risk for SCD must be evaluated in competitive athletes with previously known cardiovascular disorders or those discovered during preparticipation screening, as well as in those with known disorders who wish to participate in recreational sports. Recommendations for

the latter, based on the intensity of exercise and the nature of the disease, are available.¹⁹⁸ Issues for competing athletes are more complex, including both medical¹⁹⁹ and legal considerations.²⁰⁰

SUDDEN DEATH AND PUBLIC SAFETY

The unexpectedness of SCD has raised questions concerning secondary risk to the public created by people in the throes of cardiac arrest. No data from controlled studies are available to guide public policy regarding people at high risk for potentially lethal arrhythmias and for abrupt incapacitation. In a report of observations on 1348 sudden deaths caused by coronary heart disease in people 65 years or younger during a 7-year period in Dade County, Fla., 101 (7.5%) of the deaths occurred in people who were engaged in activities at the time of death that were potentially hazardous to the public (e.g., driving a motor vehicle, working at altitude, piloting aircraft), and 122 (9.1%) of the victims had occupations that could create potential hazards to others if an abrupt loss of consciousness had occurred while they were at work. No catastrophic events occurred as a result of these cardiac arrests, only minor property damage in 19 and minor injuries in 5.

Other studies have also led to the conclusion that risk to the public is low. In specific reference to private automobile drivers, a study from Seattle identified 33 SCDs per year while driving the estimated 1.32 million vehicles in the community. The data available suggest that unexpected cardiac arrest at the wheel usually involves a prodrome sufficient to allow the driver to get to the roadside before losing consciousness. An analysis of recurrent VT/VF events in cardiac arrest survivors has suggested limitation of driving privileges for the first 8 months after the index event on the basis of the clustering of recurrent event rates early after the index event.^{21,201} Therefore, although there are likely to be isolated cases in which cardiac arrest causes public hazards, the risk appears to be small, and because it is difficult to identify specific individuals at risk, sweeping restrictions to avoid such risks appear to be unwarranted. The exceptions are people with

multisystem disease, particularly senility, and individual circumstances that require specific consideration, such as patients with documented or substantial risk for loss of consciousness associated with the onset of arrhythmias and high-risk patients who have special responsibilities—school bus drivers, aircraft pilots, train operators, and truck drivers.²⁰¹

DEFINITION

Syncope, or transient loss of consciousness (LOC) caused by transient global cerebral hypoperfusion, is characterized by rapid onset, short duration, and spontaneous recovery.¹ LOC results from a reduction in blood flow to the reticular activating system located in the brainstem and does not require electrical or chemical therapy for reversal. The metabolism of the brain, in contrast to that of many other organs, is exquisitely dependent on perfusion. Consequently, cessation of cerebral blood flow leads to LOC within approximately 10 seconds. Restoration of appropriate behavior and orientation after a syncopal episode is usually immediate. Retrograde amnesia, though uncommon, can be present in older adults. It is important to recognize that syncope, as defined above, represents a subset of a much wider spectrum of conditions that can result in transient LOC, including conditions such as stroke and epileptic seizures. Nonsyncopal causes of transient LOC differ in their mechanism and duration.¹

Syncope is an important clinical problem because it is common, costly, and often disabling; can cause injury; and can be the only warning sign before sudden cardiac death¹⁻³ (see Chapter 39). Patients with syncope account for 1% of hospital admissions and 3% of emergency department visits. Surveys of young adults have revealed that up to 50% report a previous episode of LOC. Most of these episodes are isolated events that never come to medical attention. The prevalence of a first episode of syncope is particularly high between the ages of 10 and 20 years.⁴ Additional peaks in the prevalence of first syncopal episodes occur at approximately 60 and 80 years of age.⁴ Patients who experience syncope also report markedly reduced quality of life. Furthermore, syncope can result in traumatic injury.⁵

The prognosis of patients with syncope varies greatly with the diagnosis. Patients with syncope in the setting of structural heart disease or primary electrical disease have an increased incidence of sudden death and overall mortality. Syncope caused by orthostatic hypotension is associated with a twofold increase in mortality, which reflects the presence of multiple comorbid conditions in this patient group. In contrast, young patients with neurally mediated syncope have an excellent prognosis.

CLASSIFICATION

Shown in Tables 40-1 and 40-2 are the diagnostic considerations in patients with real or apparent transient LOC (Table 40-1) and also in those with syncope (Table 40-2). An approach to the differential

diagnosis of transient LOC is outlined in Figure 40-1.¹ Syncope can be distinguished from most other causes of transient LOC by asking whether the LOC was transient, of rapid onset, of short duration, and followed by spontaneous recovery. If the answer to each of these questions is yes and the transient LOC did not result from head trauma, the diagnostic considerations include true syncope in which the mechanism of transient LOC is global cerebral hypoperfusion, epileptic seizures, psychogenic syncope, and other rare causes. It is important to consider nonsyncopal conditions when evaluating a patient with transient LOC, such as metabolic disorders, epilepsy, or alcohol, as well as conditions in which consciousness is only apparently lost (i.e., conversion reaction). These psychogenic causes of syncope, being recognized with increased frequency, are typically diagnosed in patients 40 years or younger and especially in those with a history of psychiatric disease.

The differential diagnosis of syncope (see Table 40-2) includes vascular causes as most common, followed by cardiac causes, with arrhythmias being most frequent (see Chapter 37). Although knowledge of the common conditions that can cause syncope is essential and allows the clinician to arrive at a probable cause of the syncope in most patients, it is equally important to be aware of several less common but potentially lethal causes of syncope, such as long-QT syndrome, arrhythmogenic right ventricular dysplasia, Brugada syndrome, hypertrophic cardiomyopathy, idiopathic ventricular fibrillation (VF), catecholaminergic polymorphic ventricular tachycardia, short-QT syndrome, and pulmonary emboli⁶⁻¹¹ (see Chapter 32).

It is important to recognize that the distribution of causes of syncope varies both with patient age and with the clinical setting in which the patient is evaluated. Neurally mediated syncope and other causes of reflex-mediated syncope are the most frequent causes of syncope at any age and in any setting. Cardiac causes of syncope, especially cardiac tachyarrhythmias and bradyarrhythmias, are the second most common causes of syncope. The incidence of cardiac causes of syncope is higher in older adults and in patients evaluated in emergency departments. Orthostatic hypotension is extremely uncommon in patients younger than 40 years but is common in very elderly adults (see Chapter 76).

VASCULAR CAUSES OF SYNCOPE

Vascular causes of syncope, particularly reflex-mediated syncope and orthostatic hypotension, are by far the most common causes and account for at least a third of all syncopal episodes.^{1,2,12-21} In contrast, vascular steal syndromes are exceedingly uncommon causes of syncope.

**TABLE 40-1 Causes of Real or Apparent Transient Loss of Consciousness**

Syncope (see Table 40-2)
Neurologic or cerebrovascular disease
Epilepsy
Vertebrobasilar transient ischemic attack
Metabolic syndromes and coma
Hyperventilation with hypocapnia
Hypoglycemia
Hypoxemia
Intoxication with drugs or alcohol
Coma
Psychogenic syncope
Anxiety, panic disorder
Somatization disorders

TABLE 40-2 Causes of Syncope

Vascular
Anatomic
Vascular steal syndromes (subclavian steal syndrome)
Orthostatic
Autonomic insufficiency
Idiopathic
Volume depletion
Drug and alcohol induced

Carotid sinus hypersensitivity
Neurally mediated syncope (common faint, vasodepressor, neurocardiogenic, vasovagal)
Glossopharyngeal syncope
Situational (acute hemorrhage, cough, defecation, laugh, micturition, sneeze, swallow, postprandial)
Cardiac
Anatomic
Obstructive cardiac valve disease
Aortic dissection
Atrial myxoma
Pericardial disease, tamponade
Hypertrophic obstructive cardiomyopathy
Myocardial ischemia, infarction
Pulmonary embolism
Pulmonary hypertension
Arrhythmias
Bradyarrhythmias
Atrioventricular block
Sinus node dysfunction, bradycardia
Tachyarrhythmias
Supraventricular tachycardia
Atrial fibrillation
Paroxysmal supraventricular tachycardia (AVNRT, WPW)
Other
Ventricular tachycardia
Structural heart disease
Inherited syndromes (ARVD, HCM, Brugada syndrome, long-QT syndrome)
Drug-induced proarrhythmia
Implanted pacemaker or ICD malfunction

Syncope of Unknown Origin

AVNRT = AV nodal reentrant tachycardia; ARVD = arrhythmogenic right ventricular dysplasia; HCM = hypertrophic cardiomyopathy; WPW = Wolff-Parkinson-White syndrome.

Orthostatic Hypotension

Standing displaces 500 to 800 mL of blood to the abdomen and lower extremities, thereby resulting in an abrupt drop in venous return to the heart. This drop leads to a decrease in cardiac output and stimulation of aortic, carotid, and cardiopulmonary baroreceptors, which triggers a reflex increase in sympathetic outflow. As a result, heart rate, cardiac contractility, and vascular resistance increase to maintain stable systemic blood pressure (BP) on standing. *Orthostatic*

intolerance is a term used to refer to the signs and symptoms of an abnormality in any portion of this BP control system. Symptoms of orthostatic intolerance include syncope, lightheadedness/presyncope, tremulousness, weakness, fatigue, palpitations, diaphoresis, and blurred or tunnel vision. Orthostatic hypotension is defined as a 20-mm Hg drop in systolic BP or a 10-mm Hg drop in diastolic BP within 3 minutes of standing. Orthostatic hypotension can be asymptomatic or associated with the symptoms of orthostatic intolerance just listed. These symptoms are often worse immediately on arising in the morning or after meals or exercise. Initial orthostatic hypotension is defined as less than a 40-mm Hg decrease in BP immediately on standing with rapid return to normal (<30 seconds).¹⁷ In contrast, delayed progressive orthostatic hypotension is characterized by a slow progressive decrease in systolic BP on standing.¹⁸ Syncope that occurs after meals, particularly in elderly people, can result from a redistribution of blood to the gut. A decline in systolic BP of approximately 20 mm Hg approximately 1 hour after eating has been reported in up to a third of elderly nursing home residents. Though usually asymptomatic, it can result in lightheadedness or syncope.

Drugs that either cause volume depletion or result in vasodilation are the most common causes of orthostatic hypotension (Table 40-3). Elderly patients are particularly susceptible to the hypotensive effects of drugs because of reduced baroreceptor sensitivity, decreased cerebral blood flow, renal sodium wasting, and an impaired thirst mechanism that develops with aging. Orthostatic hypotension can also result from neurogenic causes, which can be subclassified into primary and secondary autonomic failure (see Chapter 89). Primary causes are generally idiopathic, whereas secondary causes are associated with a known biochemical or structural anomaly or are seen as part of a particular disease or syndrome.

There are three types of primary autonomic failure. Pure autonomic failure (Bradbury-Eggleston syndrome) is an idiopathic sporadic disorder characterized by orthostatic hypotension, usually in conjunction with evidence of more widespread autonomic failure such as disturbances in bowel, bladder, thermoregulatory, and sexual function. Patients with pure autonomic failure have reduced supine plasma norepinephrine levels. Multiple system atrophy (Shy-Drager syndrome) is a sporadic, progressive, adult-onset disorder characterized by autonomic dysfunction, parkinsonism, and ataxia in any combination. The third type of primary autonomic failure is Parkinson disease with autonomic failure. A small subset of patients with Parkinson disease may also experience autonomic failure, including orthostatic hypotension. In addition to these forms of chronic autonomic failure is a rare acute panautonomic neuropathy. This neuropathy generally occurs in young people and results in widespread severe sympathetic and parasympathetic failure with orthostatic hypotension, loss of sweating, disruption of bladder and bowel function, fixed heart rate, and fixed dilated pupils.

Postural orthostatic tachycardia syndrome (POTS) is a milder form of chronic autonomic failure and orthostatic intolerance characterized by the presence of symptoms of orthostatic intolerance, an increase of 28 beats/min or more in heart rate, and absence of a significant change in BP within 5 minutes of standing or upright tilt.^{1,2,14} The precise pathophysiologic basis for POTS has not been well defined. Some patients have both POTS and neurally mediated syncope.¹⁵

Reflex-Mediated Syncope

Reflex-mediated causes of syncope are listed in Table 40-2. In this group of conditions the cardiovascular reflexes that control the circulation become inappropriate in response to a trigger, which results in vasodilation with or without bradycardia and a drop in BP and global cerebral hypoperfusion. In each case the reflex is composed of a trigger (the afferent limb) and a response (the efferent limb). This group of reflex-mediated syncopal syndromes has in common the response limb of the reflex, which consists of increased vagal tone and withdrawal of peripheral sympathetic tone and leads to bradycardia, vasodilation, and ultimately, hypotension, presyncope, or

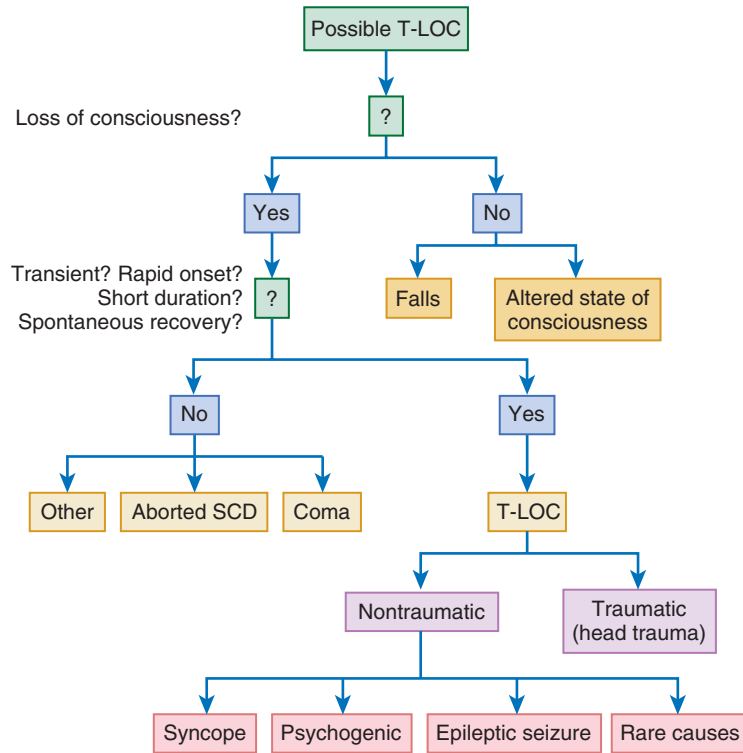

FIGURE 40-1 Approach to the evaluation of patients with transient loss of consciousness (T-LOC). SCD = sudden cardiac death.

TABLE 40-3 Causes of Orthostatic Hypotension

Drugs	Secondary Neurogenic
Diuretics	Aging
Alpha-adrenergic blocking drugs	Autoimmune disease
Terazosin (Hytrin), labetalol	Guillain-Barré syndrome, mixed connective tissue disease, rheumatoid arthritis
Adrenergic neuron blocking drugs	Eaton-Lambert syndrome, systemic lupus erythematosus
Guanethidine	Carcinomatosis autonomic neuropathy
Angiotensin-converting enzyme inhibitors	Central brain lesions
Antidepressants	Multiple sclerosis, Wernicke encephalopathy
Monoamine oxidase inhibitors	Vascular lesions or tumors involving the hypothalamus and midbrain
Alcohol	Dopamine beta-hydroxylase deficiency
Diuretics	Familial hyperbradykinesia
Ganglion blocking drugs	General medical disorders
Hexamethonium, mecamylamine	Diabetes, amyloid, alcoholism, renal failure
Tranquilizers	Hereditary sensory neuropathies, dominant or recessive
Phenothiazines, barbiturates	Infections of the nervous system
Vasodilators	Human immunodeficiency virus infection, Chagas disease, botulism, syphilis
Prazosin, hydralazine, calcium channel blockers	Metabolic disease
Centrally acting hypotensive drugs	Vitamin B ₁₂ deficiency, porphyria, Fabry disease, Tangier disease
Methyldopa, clonidine	Spinal cord lesions
Primary Disorders of Autonomic Failures	
Pure autonomic failure (Bradbury-Eggleston syndrome)	
Multiple system atrophy (Shy-Drager syndrome)	
Parkinson disease with autonomic failure	

Modified from Bannister SR (ed): *Autonomic Failure*. 2nd ed. Oxford, Oxford University Press, 1988, p 8.

syncope. If hypotension secondary to peripheral vasodilation predominates, it is classified as a vasodepressor-type reflex response; if bradycardia and/or asystole predominates, it is classified as a cardio-inhibitory response; and when both vasodilation and bradycardia play a role, it is classified as a mixed response. What distinguish these causes of syncope are the specific triggers. For example, micturition-induced syncope results from activation of mechanoreceptors in the bladder, defecation-induced syncope results from neural input from gut wall tension receptors, and swallowing-induced syncope results from afferent neural impulses arising from the upper gastrointestinal tract. The two most common types of reflex-mediated syncope, carotid sinus hypersensitivity and neurally mediated hypotension,

are discussed later. Identification of the trigger is of importance because of its therapeutic implications, with avoidance of the trigger possibly preventing further syncopal episodes.

Neurally Mediated Hypotension or Syncope (Vasovagal Syncope)

The term *neurally mediated hypotension* or *syncope* (also known as neurocardiogenic, vasodepressor, and vasovagal syncope and “fainting”) has been used to describe a common abnormality in regulation of BP characterized by an abrupt onset of hypotension with or without bradycardia. Triggers associated with the development of

neurally mediated syncope include orthostatic stress, such as can occur with prolonged standing or a hot shower, and emotional stress, such as can result from the sight of blood.^{1,2,13,16} A large proportion of patients with neurally mediated syncope may have minor psychiatric disorders.¹⁹ It has been proposed that neurally mediated syncope results from a paradoxical reflex that is initiated when ventricular preload is reduced by venous pooling. This reduction leads to a decrease in cardiac output and BP, which is sensed by arterial baroreceptors. The resultant increased catecholamine levels, combined with reduced venous filling, leads to a vigorously contracting, volume-depleted ventricle. The heart itself is involved in this reflex by virtue of the presence of mechanoreceptors, or C fibers, consisting of non-myelinated fibers found in the atria, ventricles, and pulmonary artery. It has been proposed that vigorous contraction of a volume-depleted ventricle leads to activation of these receptors in susceptible individuals. These afferent C fibers project centrally to the dorsal vagal nucleus of the medulla and can result in “paradoxical” withdrawal of peripheral sympathetic tone and an increase in vagal tone, which in turn causes vasodilation and bradycardia. The ultimate clinical consequence is syncope or presyncope. Not all neurally mediated syncope results from activation of mechanoreceptors, however. In humans, the sight of blood or extreme emotion can trigger syncope, thus suggesting that higher neural centers can also participate in the pathophysiology of vasovagal syncope. In addition, central mechanisms can contribute to the production of neurally mediated syncope.

Carotid Sinus Hypersensitivity

Syncope caused by *carotid sinus hypersensitivity* results from stimulation of carotid sinus baroreceptors located in the internal carotid artery above the bifurcation of the common carotid artery. Carotid sinus hypersensitivity is detected in approximately a third of elderly patients evaluated for syncope or falls.^{1,2,20} It is important, however, to recognize that carotid sinus hypersensitivity is also commonly observed in asymptomatic elderly patients. Thus, the diagnosis of carotid sinus hypersensitivity should be approached cautiously after excluding alternative causes of the syncope. Once diagnosed, dual-chamber pacemaker implantation is recommended for patients with recurrent syncope or falls resulting from carotid sinus hypersensitivity.²² The American Heart Association/American College of Cardiology/Heart Rhythm Society guidelines for device implantation have given this a class I indication for pacemaker implantation.²² If the diagnosis of carotid sinus hypersensitivity is based on longer than a 3-second pause with carotid sinus massage without clear, provocative events, pacemaker implantation is less strongly recommended (class IIA).

CARDIAC CAUSES OF SYNCOPES

Cardiac causes of syncope, particularly tachyarrhythmias and bradyarrhythmias, are the second most common cause of syncope and account for 10% to 20% of syncopal episodes (see [Table 40-2](#) and [Chapter 39](#)). Ventricular tachycardia (VT) is the most common tachyarrhythmia that can cause syncope. Supraventricular tachycardia (SVT) can also cause syncope, although the great majority of patients with supraventricular arrhythmias have less severe symptoms such as palpitations, dyspnea, and lightheadedness. Bradyarrhythmias that can result in syncope include sick sinus syndrome and atrioventricular (AV) block. Anatomic causes of syncope include obstruction to blood flow, such as massive pulmonary embolism (see [Chapter 73](#)), atrial myxoma (see [Chapter 69](#)), or aortic stenosis (see [Chapter 63](#)).

NEUROLOGIC CAUSES OF TRANSIENT LOSS OF CONSCIOUSNESS

Neurologic causes of transient LOC, including migraines, seizures, Arnold-Chiari malformations, and transient ischemic attacks, are surprisingly uncommon and account for less than 10% of all cases of

syncope (see [Chapters 59 and 87](#)). Most patients in whom a “neurologic” cause of transient LOC is established are in fact found to have had a seizure rather than true syncope.

METABOLIC CAUSES OF TRANSIENT LOSS OF CONSCIOUSNESS

Metabolic causes of transient LOC are rare and account for less than 5% of syncopal episodes. The most common metabolic causes of syncope are hypoglycemia (see [Chapter 61](#)), hypoxia, and hyperventilation. Establishing hypoglycemia as the cause of apparent LOC requires demonstration of hypoglycemia during the syncopal episode. Although hyperventilation-induced syncope has generally been considered to be due to a reduction in cerebral blood flow, one study demonstrated that hyperventilation alone was not sufficient to cause syncope. This observation suggests that hyperventilation-induced syncope may also have a psychological component. Psychiatric disorders can also cause syncope. Up to a fourth of patients with syncope of unknown origin may have psychiatric disorders for which apparent syncope is one of the initial symptoms^{1,2} (see [Chapter 86](#)).

DIAGNOSTIC TESTS

Identification of the precise cause of the syncope is often challenging. Because syncope usually occurs sporadically and infrequently, it is extremely difficult to either examine a patient or obtain an electrocardiogram (ECG) during an episode of syncope. For this reason, the primary goal in the evaluation of a patient with syncope is to arrive at a presumptive determination of the cause of the syncope.

History, Physical Examination, and Carotid Sinus Massage

The history and physical examination are by far the most important components of the evaluation of a patient with transient LOC and syncope and can be used to identify the cause in more than 25% of patients.^{1,2,12,23} Maximal information can be obtained from the clinical history when it is approached in a systematic and detailed fashion. Initial evaluation should begin by determining whether the patient did in fact experience a syncopal episode by asking the following: (1) Did the patient experience complete LOC? (2) Was the LOC transient with a rapid onset and short duration? (3) Did the patient recover spontaneously, completely, and without sequelae? and (4) Did the patient lose postural tone? If the answer to one or more of these questions is negative, other nonsyncopal causes of transient LOC should be suspected. Although falls can be differentiated from syncope by the absence of LOC, an overlap between symptoms of falls and syncope has been reported^{1,2} because elderly individuals may experience amnesia for the LOC episode. When evaluating a patient with syncope, particular attention should then be focused on (1) determining whether the patient has a history of cardiac disease or metabolic disease (i.e., diabetes) or a family history of cardiac disease, syncope, or sudden death; (2) identifying medications that may have played a role in syncope, especially those that may cause hypotension, bradycardia/heart block, or a proarrhythmic response (antiarrhythmic medications); (3) quantifying the number and chronicity of previous syncopal and presyncopal episodes; (4) identifying precipitating factors, including body position and activity immediately before syncope; and (5) quantifying the type and duration of prodromal and recovery symptoms. It is also useful to obtain careful accounts from witnesses to provide a detailed description of the episode, including how the patient collapsed and the patient's skin color and breathing pattern, duration of unconsciousness, and movements during the episode of unconsciousness. Features of the clinical history most helpful in differentiating neurally mediated hypotension, arrhythmia, seizures, and psychogenic syncope are summarized in [Table 40-4](#).

The clinical histories obtained from patients with syncope related to AV block and VT are similar. In each case, syncope typically occurs with less than 5 seconds of warning and few if any prodromal and recovery symptoms. Demographic features suggesting that the

TABLE 40-4 Differentiation of Syncope Caused by Neurally Mediated Hypotension, Arrhythmias, Seizures, and Psychogenic Causes

	NEURALLY MEDIATED HYPOTENSION	ARRHYTHMIAS	SEIZURES	PSYCHOGENIC
Demographics and clinical setting	Female > male sex Younger age (<55 yr) More episodes (>2) Standing, warm room, emotional upset	Male > female sex Older age (>54 yr) Fewer episodes (<3) During exertion or supine Family history of sudden death	Younger age (<45 yr) Any setting	Female > male sex Occurs in the presence of others Younger age (<40 yr) Many episodes (often many episodes in a day) No identifiable trigger
Premonitory symptoms	Longer duration (>5 sec) Palpitations Blurred vision Nausea Warmth Diaphoresis Lightheadedness	Shorter duration (<6 sec) Palpitations less common	Sudden onset or brief aura (déjà vu, olfactory, gustatory, visual)	Usually absent
Observations during the event	Pallor Diaphoresis Dilated pupils Slow pulse, low BP Incontinence may occur Brief clonic movements may occur	Blue, not pale Incontinence can occur Brief clonic movements can occur	Blue face, no pallor Frothing at the mouth Prolonged syncope (duration >5 min) Tongue biting Horizontal eye deviation Elevated pulse and BP Incontinence more likely* Tonic-clonic movements if grand mal	Normal color Not diaphoretic Eyes closed Normal pulse and BP No incontinence Prolonged duration (minutes) is common
Residual symptoms	Residual symptoms common Prolonged fatigue common (>90%) Oriented	Residual symptoms uncommon (unless prolonged unconsciousness) Oriented	Residual symptoms common Aching muscles Disoriented Fatigue Headache Slow recovery	Residual symptoms uncommon Oriented

*May be observed with any of these causes of syncope but more common with seizures.

syncope results from an arrhythmia such as VT or AV block include male sex, fewer than three previous episodes of syncope, and increased age. Features of the clinical history that point toward a diagnosis of neurally mediated syncope include palpitations, blurred vision, nausea, warmth, diaphoresis, or lightheadedness before syncope and the presence of nausea, warmth, diaphoresis, or fatigue after syncope.

Features of the clinical history useful in distinguishing seizures from syncope include orientation following an event, a blue face or not becoming pale during the event, frothing at the mouth, aching muscles, feeling sleepy after the event, and a duration of unconsciousness of longer than 5 minutes. Tongue biting strongly points toward a seizure rather than syncope as the cause of LOC. One recent study reported that a history of tongue biting during an episode of LOC had 33% sensitivity and 96% specificity in predicting a seizure as the cause of the LOC.²⁴ Other findings suggestive of a seizure as a cause of the syncopal episode include (1) an aura before the episode, (2) horizontal eye deviation during the episode, (3) elevated BP and pulse during the episode, and (4) a headache following the event. Urinary or fecal incontinence can be observed with either a seizure or a syncopal episode but occurs more commonly with a seizure. Grand mal seizures are usually associated with tonic-clonic movements. It is important to note that syncope caused by cerebral ischemia can result in decorticate rigidity with clonic movements of the arms. Akinetic or petit mal seizures can be recognized by the patient's lack of responsiveness in the absence of loss of postural tone. Temporal lobe seizures last several minutes and are characterized by confusion, changes in LOC, and autonomic signs such as flushing. Vertebral basilar insufficiency should be considered as the cause of the syncope if it occurs in association with other symptoms of brain-stem ischemia (i.e., diplopia, tinnitus, focal weakness or sensory loss, vertigo, or dysarthria). Migraine-mediated syncope is often associated with a throbbing unilateral headache, scintillating scotomata, and nausea.

Physical Examination

In addition to a complete cardiac examination, particular attention should be focused on whether structural heart disease is present, defining the patient's level of hydration, and detecting the presence of significant neurologic abnormalities suggestive of dysautonomia or a cerebrovascular accident. Orthostatic vital signs are a critical component of the evaluation. The patient's BP and heart rate should be determined while supine and then repeated each minute for approximately 3 minutes while standing. The two abnormalities that should be searched for are (1) early orthostatic hypotension, defined as a 20-mm Hg drop in systolic BP or a 10-mm Hg drop in diastolic BP within 3 minutes of standing, and (2) POTS, which is defined as an increase of 28 beats/min or greater within 5 minutes of standing along with symptoms of orthostatic intolerance. The significance of POTS lies in its close overlap with neurally mediated syncope.

Carotid Sinus Massage

Carotid sinus massage should be performed after checking for bruits in patients older than 40 years with syncope by applying gentle pressure over the carotid pulsation, first one side and then the other, just below the angle of the jaw where the carotid bifurcation is located. Pressure should be applied for 5 to 10 seconds in both the supine and upright positions because an abnormal response to carotid sinus massage is present only in the upright position in up to a third of patients. Since the main complications associated with performing carotid sinus massage are neurologic, carotid sinus massage should be avoided in patients with previous transient ischemic attacks, strokes within the past 3 months, and carotid bruits, except if significant stenosis has been excluded by carotid Doppler studies. A normal response to carotid sinus massage is a transient decrease in the sinus rate, prolongation of AV conduction, or both. Carotid sinus hypersensitivity is defined as a sinus pause longer than 3 seconds in duration and/or a fall in systolic BP of 50 mm Hg or greater. The response to carotid sinus massage can be classified as cardioinhibitory

(asystole), vasodepressive (fall in systolic BP), or mixed. Diagnosis of carotid sinus hypersensitivity as the cause of the syncope requires reproduction of the patient's symptoms during carotid sinus massage.

Laboratory Tests

Blood Tests

Routine use of blood tests, such as serum electrolytes, cardiac enzymes, glucose, and hematocrit levels, is of low diagnostic value in syncopal patients and therefore not recommended routinely.

Tilt-Table Testing

The tilt-table test is a valuable diagnostic test for evaluating patients with syncope,^{1,2,13,16,25} with a positive response indicating susceptibility to neurally mediated syncope. Upright tilt testing is generally performed for 30 to 45 minutes following a 20-minute horizontal pre-tilt stabilization phase at an angle between 60 and 80 degrees (with 70 degrees being most common). The sensitivity of the test can be increased, along with an associated fall in specificity, by the use of longer tilt durations, steeper tilt angles, and provocative agents such as isoproterenol or nitroglycerin. When isoproterenol is used as a provocative agent, it is recommended that the infusion rate be increased incrementally from 1 to 3 µg/min to increase the heart rate 25% greater than baseline. When nitroglycerin is used, a fixed dose of 300 to 400 µg nitroglycerin spray should be administered sublingually after a 20-minute unmedicated phase with the patient in the upright position. These two provocative approaches are equivalent in diagnostic accuracy. In the absence of pharmacologic provocation, the specificity of the test has been estimated to be 90%; when provocative agents are used, specificity decreases significantly.

The main indication for upright tilt testing is to confirm a diagnosis of neurally mediated syncope when the initial evaluation was insufficient to establish this diagnosis. Upright tilt testing is not generally recommended in patients in whom the diagnosis can be established from the initial history and physical examination. However, for some patients, confirmation of the diagnosis with a positive response to upright tilt testing is very reassuring. Induction of reflex hypotension/bradycardia without reproduction of the syncope points toward a diagnosis of neurally mediated syncope but is a less specific response. If a patient has structural heart disease, other cardiovascular causes of syncope should be excluded before considering a positive response to upright tilt testing to be diagnostic of neurally mediated syncope. Upright tilt testing is also indicated in the evaluation of patients for whom the cause of the syncope has been determined (i.e., asystole) but the presence of neurally mediated syncope on upright tilt would influence treatment. Upright tilt testing has also been shown to be of value in patients with psychogenic causes of syncope in that it may trigger LOC in association with a normal BP and heart rate. Induction of LOC with no change in vital signs points strongly toward a diagnosis of psychogenic pseudosyncope. Upright tilt testing has no value in assessing the efficacy of treatment of neurally mediated syncope.

Echocardiography

Echocardiograms are commonly used to evaluate patients with syncope, but current guidelines suggest that an echocardiogram should be performed only in patients suspected of having structural heart disease.^{1,2,12} For example, an echocardiogram should be obtained in patients who have clinical features suggestive of a cardiac cause of the syncope, such as syncope with exertion or while supine, a family history of sudden death, and/or syncope of abrupt onset. Echocardiographic findings considered diagnostic of the cause of syncope include severe aortic stenosis, pericardial tamponade, aortic dissection, congenital abnormalities of the coronary arteries, and obstructive atrial myxomas or thrombi. Findings of impaired right or left ventricular function, evidence of right ventricular overload or pulmonary hypertension (pulmonary emboli), or the presence of hypertrophic cardiomyopathy (see Chapter 66) are of prognostic importance and justify additional diagnostic testing.

Stress Tests and Cardiac Catheterization

Myocardial ischemia is an unlikely cause of syncope and, when present, is usually accompanied by angina (see Chapter 49). The use of stress tests (see Chapter 13) is best reserved for patients in whom syncope or presyncope occurred during or immediately after exertion in association with chest pain or in a patient at high risk for coronary artery disease.^{1,2,12} Syncope occurring during exercise is suggestive of a cardiac cause. In contrast, syncope following exercise is usually caused by neurally mediated syncope. Even in patients with syncope during exertion, exercise stress testing is highly unlikely to trigger another event. Coronary angiography is recommended in patients with syncope suspected to be due, directly or indirectly, to myocardial ischemia.

Electrocardiography

The 12-lead ECG is another important component in the workup of a patient with syncope (see Chapter 12). The initial ECG results in establishment of a diagnosis in approximately 5% of patients and suggests a diagnosis in another 5% of patients. Specific findings that can identify the probable cause of the syncope include QT prolongation (long-QT syndrome), the presence of a short PR interval and a delta wave (Wolff-Parkinson-White syndrome), the presence of a right bundle branch block pattern with ST-segment elevation (Brugada syndrome), evidence of acute myocardial infarction, high-grade AV block, or T wave inversion in the right precordial leads (arrhythmogenic right ventricular dysplasia). Any abnormal finding on the baseline ECG is an independent predictor of cardiac syncope or increased mortality and suggests the need to pursue evaluation of cardiac causes of syncope.^{1,2} Most patients with syncope have normal findings on ECGs, which is useful because it suggests a low likelihood of a cardiac cause of the syncope and is associated with an excellent prognosis, particularly when observed in a young patient with syncope. Despite the low diagnostic yield of electrocardiography, the test is inexpensive and risk free and is considered a standard part of the evaluation of virtually all patients with syncope.^{1,2,12}

Signal-Averaged Electrocardiography

Signal-averaged electrocardiography (SAECG) (see Chapter 34) is a noninvasive technique used to detect low-amplitude signals in the terminal portion of the QRS complex (late potentials), which are a substrate for ventricular arrhythmias. In contrast to a standard ECG, the role of SAECG in the evaluation of patients with syncope is not well established and it is not recommended as a standard part of the evaluation of patients with syncope.^{1,2,12} One of the few situations in which SAECG is of diagnostic value is when a diagnosis of arrhythmogenic right ventricular dysplasia is being considered.⁷

Holter Recording and Telemetry

Continuous ECG monitoring via telemetry or Holter monitoring (see Chapter 34) is commonly performed in patients with syncope but is unlikely to identify the cause of the syncope. The information provided by ECG monitoring at the time of syncope is extremely valuable in that it allows an arrhythmic cause of syncope to be established or excluded. However, because of the infrequent and sporadic nature of syncope, the diagnostic yield of Holter monitoring in the evaluation of patients with syncope and presyncope is extremely low. Another clinically useful finding is detection of symptoms in the absence of an arrhythmia, which is observed in up to 15% of patients undergoing continuous ECG monitoring. It is important to emphasize that the absence of an arrhythmia and symptoms during continuous ECG monitoring may not exclude an arrhythmia as the cause of the syncope. In patients suspected of having an arrhythmia as the cause of the syncope, additional evaluation such as electrophysiologic (EP) testing or event monitoring should be considered. Inpatient telemetry monitoring and/or Holter monitoring is recommended for patients who have clinical or ECG features suggesting an arrhythmic syncope or a history of recurrent syncope with injury. Holter monitoring and inpatient telemetry monitoring are most likely to be diagnostic when

used for the occasional patient with frequent (i.e., daily) episodes of syncope or presyncope.

Event Recorders

Some transtelephonic event monitors (see Chapter 34) are worn continuously to capture both retrospective and prospective ECG recordings, whereas other types record only when they are activated by the patient. Continuous-loop event monitors, often programmed with 5 to 15 minutes of preactivation memory stored by the device, are preferred because the data can be retrieved for analysis. Prospective event monitors not worn continuously by the patient are of value to investigate palpitations but play no role in the evaluation of patients with syncope. Event monitors are indicated in the early phase of the evaluation of patients with syncope of uncertain origin who do not have high-risk criteria that require immediate hospitalization or intensive evaluation. They are also indicated in high-risk patients in whom a comprehensive evaluation did not demonstrate a cause of the syncope or lead to specific treatment.^{1,2,12,26} Over the past 5 years, external and implantable devices for real-time outpatient telemetry monitoring have been developed with wireless cell phone–like technology to transmit real-time ECG recordings to a service center. Studies have demonstrated that these devices result in higher diagnostic yield in patients with syncope or presyncope than do the conventional event monitors just described.²⁷

Implantable Event Recorders

In patients with extremely infrequent episodes of syncope (e.g., once or twice a year), a traditional event monitor is unlikely to record an event. Implantable event recorders address this problem by triggering automatically on the basis of programmed detection criteria, as well as with a handheld activator, and storing the ECG signal in a circular buffer (see Chapter 34). Some of these devices can transmit the signals transtelephonically. These devices allow a longer monitoring period (12 to 36 months) and have higher diagnostic yield, but they have the disadvantages of requiring surgical implantation and

increased cost. A recent advancement in this technology is that these implantable event monitors can be accessed by remote monitoring, which further increases their diagnostic effectiveness.²⁸

Current guidelines recommend that when the mechanism of the syncope remains unclear after a full evaluation, an implantable event recorder is indicated in patients who have clinical or ECG features suggesting arrhythmic syncope or a history of recurrent syncope with injury.^{1,2,26} An implantable event monitor can also be used early in the evaluation of patients who do not have high-risk features of syncope that require hospitalization or intensive evaluation.²⁶ An implantable event recorder can also be used to assess the contribution of bradycardia before implanting a permanent pacemaker in patients with suspected or certain neurally mediated syncope who have frequent or traumatic syncopal episodes.

Electrophysiologic Testing

EP testing (see Chapter 34) can provide important diagnostic information in patients with syncope by establishing a diagnosis of sick sinus syndrome, carotid sinus hypersensitivity, heart block, SVT, and VT. Indications for EP testing and diagnostic findings in the evaluation of patients with syncope are shown in Table 40-5.¹ It is generally agreed that EP testing should be performed in patients when the initial evaluation suggests an arrhythmic cause of the syncope,^{1,2,12} such as those with abnormal findings on an ECG and/or structural heart disease, those whose clinical history suggests an arrhythmic cause of the syncope, and those with a family history of sudden death. EP testing should not be performed in patients with normal findings on an ECG and no heart disease and in whom the clinical history does not suggest an arrhythmic cause of the syncope. The class II indications for performing an electrophysiologic study (EPS) are shown in Table 40-5, which indicates that EP testing is appropriate when the results may have an impact on treatment and also in patients with “high-risk” occupations, in whom every effort should be expended to determine the probable cause of the syncope. EP

TABLE 40-5 Indications for and Diagnostic Findings of Electrophysiologic Testing in the Evaluation of Patients with Syncope

	CLASS	LEVEL OF EVIDENCE
Indications		
In patients with ischemic heart disease when the initial evaluation suggests an arrhythmic cause and there is no established indication for an ICD	I	B
In patients with BBB, EPS should be considered when noninvasive tests do not establish a diagnosis	IIa	B
In patients with syncope preceded by sudden and brief palpitations when noninvasive tests do not establish a diagnosis	IIb	B
In patients with syncope and Brugada syndrome, ARVD, or hypertrophic cardiomyopathy, EPS is appropriate in selected cases	IIb	C
In patients with high-risk occupations, in whom every effort to exclude a cardiovascular cause of syncope is warranted	IIb	C
EPS is not recommended in syncopal patients with normal findings on an ECG, heart disease, and no palpitations	III	B
Diagnostic Criteria		
EPS is diagnostic and no additional tests are required in the following situations:		
Sinus bradycardia and a prolonged CSNRT (>525 msec)	I	B
BBB and either a baseline HV interval ≥100 msec or second- or third-degree His-Purkinje block during incremental atrial pacing or with pharmacologic challenge	I	B
Induction of sustained monomorphic VT in patients with a previous myocardial infarction	I	B
Induction of SVT with reproduction of the hypotensive or spontaneous symptoms	I	B
HV interval between 70 and 100 msec should be considered diagnostic	IIa	B
Induction of polymorphic VT or VF in patients with Brugada syndrome, patients with ARVD, or patients resuscitated from cardiac arrest	IIb	B
Induction of polymorphic VT or VF in patients with ischemic disease or DCM should not be considered a diagnostic finding	III	B

ARVD = arrhythmogenic right ventricular dysplasia; BBB = bundle branch block; DCM = dilated cardiomyopathy; EPS = electrophysiologic study.

Modified from Moya A, Sutton R, Ammirati F, et al: Guidelines for the diagnosis and management of syncope 2009. *Eur Heart J* 30:2631, 2009.

testing is no longer indicated for patients with a severely depressed ejection fraction, because in this setting an implantable cardioverter-defibrillator (ICD) is indicated regardless of the presence or mechanism of the syncope.¹

Electrophysiologic Testing Protocol

A comprehensive EP evaluation should be performed in patients with syncope, including evaluation of sinus node function by measuring the sinus node recovery time (SNRT) and evaluation of AV conduction by measurement of the His-ventricular (H-V) interval at baseline, with atrial pacing, and following pharmacologic challenge with intravenous procainamide. In addition, programmed electrical stimulation via standard techniques should be performed to evaluate the inducibility of ventricular and supraventricular arrhythmias. Although the minimal suggested EP protocol includes only double extra stimuli and two basic drive train cycle lengths, it is common practice in the United States to include triple extra stimuli and three basic drive train cycle lengths. It is also common practice to limit the shortest coupling interval to 200 msec. In select patients in whom suspicion for ventricular arrhythmia is high, EP testing with atrial and ventricular programmed stimulation may be repeated following an infusion of isoproterenol, which is of particular importance for patients suspect of having a supraventricular arrhythmia such as AV nodal reentrant tachycardia or orthodromic AV reciprocating tachycardia as the cause of the syncope.

Sinus node function is evaluated during EP testing primarily by determining the SNRT. Identification of sinus node dysfunction as the cause of syncope is uncommon during EP tests (<5%). The sensitivity of an abnormal SNRT or corrected SNRT (CSNRT) is approximately 50% to 80%. The specificity of an abnormal SNRT or CSNRT is less than 95%.² It is important to note that the absence of evidence of sinus node dysfunction during EP testing does not exclude a bradyarrhythmia as the cause of the syncope.

During EP testing, AV conduction is assessed by measuring the AV nodal to His bundle conduction time (A-H interval) and the His bundle to ventricular conduction time (H-V interval) and also by determining the response of AV conduction to incremental atrial pacing and atrial premature stimuli. If the results of an initial assessment of AV conduction in the baseline state are inconclusive, procainamide (10 mg/kg) can be administered intravenously and atrial pacing and programmed stimulation repeated. According to the 2004 European guidelines on management of syncope,¹ findings on an EPS that allow heart block to be established as the probable cause of the syncope are bundle branch block and a baseline HV interval of 100 milliseconds or longer or demonstration of second- or third-degree His-Purkinje block during incremental atrial pacing or provoked by an infusion of procainamide (see Table 40-5). These guidelines indicate that an H-V interval of between 70 and 100 milliseconds is of less certain diagnostic value. In studies of EP testing to evaluate patients with syncope, AV block was identified as the probable cause of syncope in approximately 10% to 15% of patients.

Although it is uncommon for SVT to result in syncope, this is an important diagnosis to establish because most types of supraventricular arrhythmias can be cured with catheter ablation (see Chapter 35). The usual setting in which SVT causes syncope is in a patient with underlying heart disease and/or limited cardiovascular reserve, a patient with SVT of abrupt onset and with an extremely rapid rate, or a patient who has a propensity for the development of neurally mediated syncope. The typical pattern is the development of syncope or near-syncope at the onset of the SVT because of an initial drop in BP. The patient often regains consciousness despite continuation of the arrhythmia as a result of activation of a compensatory mechanism. Completion of a standard EP test allows accurate identification of most types of supraventricular arrhythmias that may have caused the syncope, and it should be repeated during an isoproterenol infusion to increase the sensitivity of the study, particularly for detecting AV nodal reentrant tachycardia in a patient with dual AV node physiology or catecholamine-sensitive atrial fibrillation. According to the 2009 European guidelines on management of syncope, an EPS is considered diagnostic of SVT as the cause of syncope when induction of a rapid supraventricular arrhythmia reproduces the hypotensive or spontaneous symptoms¹ (see Table 40-5). A supraventricular arrhythmia is diagnosed as the probable cause of syncope in fewer

than 5% of patients who undergo EP testing for evaluation of syncope of unknown origin, but the probability is increased in patients who report a history of palpitations/heart racing before syncope.

VT is the most common abnormality uncovered during EP testing in patients with syncope and was identified as the probable cause in approximately 20% of patients. In general, an EP test is interpreted as positive for VT when sustained monomorphic VT is induced. Induction of polymorphic VT and VF may represent a nonspecific response to EP testing. The diagnostic and prognostic importance of induction of polymorphic VT and/or VF remains uncertain. According to the 2004 European guidelines on management of syncope, an EPS is considered diagnostic of VT as the cause of the syncope when sustained monomorphic VT is induced (see Table 40-5),¹ with less certain diagnostic value with induction of polymorphic VT or VF in patients with Brugada syndrome or arrhythmogenic right ventricular dysplasia and in patients resuscitated from cardiac arrest. The role of EP testing and pharmacologic challenge with procainamide in syncope patients with suspected Brugada syndrome is controversial.²⁹

Overall, approximately a third of patients with syncope referred for diagnostic EP testing have a presumptive diagnosis established.

Test to Screen for Neurologic Causes of Syncope

Syncope as an isolated symptom rarely has a neurologic cause. As a result, widespread use of tests to screen for neurologic conditions is rarely diagnostic.^{1,2,12} In many institutions, computed tomography (CT) scans, electroencephalograms (EEGs), and carotid duplex scans are overused; they are obtained in more than 50% of patients with syncope. A diagnosis is almost never uncovered that was not first suspected on the basis of a careful history and neurologic examination. Transient ischemic attacks that result from carotid disease are not accompanied by LOC. No studies have suggested that carotid Doppler ultrasonography is beneficial in patients with syncope. EEGs should be obtained only in patients with a relatively high likelihood of epilepsy. CT and magnetic resonance imaging (see Chapters 17 and 18) should be avoided in patients with uncomplicated syncope. Although the low diagnostic yield of screening "neurologic tests" has been recognized for more than a decade, they continue to be overused and result in a dramatic increase in costs.

APPROACH TO THE EVALUATION OF PATIENTS WITH SYNCOPES

Figure 40-2 outlines the approach to the diagnostic evaluation of a patient with transient LOC proposed by the European Society of Cardiology Task Force on Syncope.¹ The initial evaluation begins with a careful history, physical examination, supine and upright BP, and a 12-lead ECG, followed by additional testing in selected patient subgroups, including carotid sinus massage, echocardiography, ECG monitoring, and tilt-table testing as discussed earlier. The various types of neurologic testing are generally of little or no value except in the case of head trauma and when nonsyncopal causes of transient LOC such as epilepsy are suspected.

Based on this initial evaluation, patients can be classified into those with true syncope and those with nonsyncopal transient LOC. Patients with syncope can be further divided into two groups: those in whom a certain diagnosis has been established and in whom treatment can be initiated and those with an uncertain diagnosis. For the latter, attention should focus on determining whether the patient is at increased risk for a cardiovascular event or death. These patients should be hospitalized and/or undergo an intensive timely outpatient cardiovascular evaluation that may include exercise stress testing, cardiac catheterization, and EP testing (Table 40-6). Conversely, patients who have experienced only a single episode of syncope and are determined to be at low risk for a cardiovascular event or death may require no further evaluation. Patients who fall between these two extremes can undergo further testing selected on the basis of results of the initial evaluation (see Fig. 40-2). When this diagnostic approach has been completed, a probable cause of syncope can be determined in more than three fourths of patients.

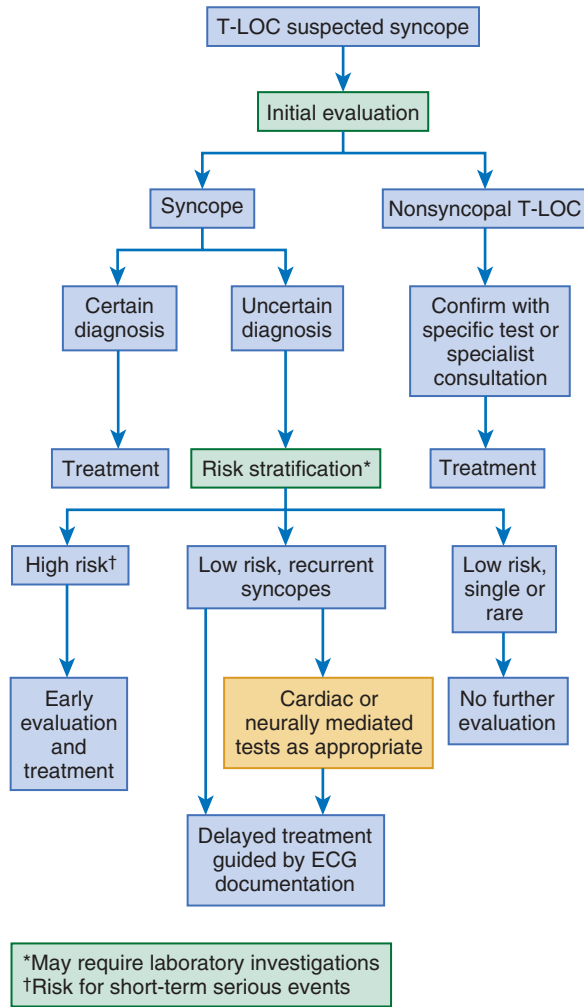

FIGURE 40-2 Diagnostic approach to the evaluation of patients with transient loss of consciousness (T-LOC) and syncope.

TABLE 40-6 Clinical Variables for Identification of High-Risk Syncope Patients Who May Benefit from Hospitalization or an Accelerated Outpatient Evaluation

Severe structural heart disease (low ejection fraction, previous myocardial infarction, heart failure)
Clinical or ECG features suggesting arrhythmic syncope
Syncope during exertion or while supine
Palpitations at the time of syncope
Family history of sudden death
Nonsustained VT
Bifascicular block or QRS >120 msec
Severe sinus bradycardia (<50 beats/min) in the absence of medications or physical training
Preexcitation
Prolonged or very short QT interval
Brugada ECG pattern (right bundle branch block with ST elevation in leads V ₁ -V ₃)
Arrhythmogenic right ventricular dysplasia ECG pattern (T wave inversion in leads V ₁ -V ₃ with or without epsilon waves)
ECG suggestive of hypertrophic dilated cardiomyopathy
Clinical evidence or suspicion of a pulmonary embolus (clinical setting, sinus tachycardia, shortness of breath)
Severe anemia
Important comorbid conditions
Significant electrolyte abnormalities
Severe anemia

The European guidelines on management of syncope have recently called attention to the importance of a structured care pathway in the evaluation of patients with syncope.¹ Other studies have reported favorable outcomes when a syncope evaluation unit or standardized approach to the evaluation of syncope is used.³⁰

MANAGEMENT OF PATIENTS

Treatment of a patient with syncope has three goals: (1) prolong survival, (2) prevent traumatic injuries, and (3) prevent recurrences of syncope. The approach to treatment of a patient with syncope depends largely on the cause and mechanism of the syncope. For example, the appropriate treatment of a patient with syncope related to AV block would be a pacemaker in most situations. However, a patient with syncope secondary to heart block in the setting of an inferior wall myocardial infarction will not usually require a permanent pacemaker because the heart block usually resolves spontaneously. Similarly, heart block resulting from neurally mediated syncope does not generally require pacemaker implantation. Treatment of a patient with syncope related to Wolff-Parkinson-White syndrome typically involves catheter ablation, and treatment of a patient with syncope related to VT or in the setting of ischemic or nonischemic cardiomyopathy would probably involve placement of an implantable defibrillator (see Chapter 36). However, ICD implantation may not be required for patients with VT/VF occurring within 48 hours of an acute myocardial infarction. For other types of syncope, optimal management may involve discontinuation of an offending pharmacologic agent, an increase in salt intake, or education of the patient.

Other issues that need to be considered include the indication for hospitalization of a patient with syncope and the duration of driving restrictions. Current guidelines recommend that patients with syncope be hospitalized when there is known or suspected heart disease, ECG abnormalities suggestive of arrhythmic syncope, syncope with severe injury or during exercise, and syncope in patients with a family history of sudden death (see Table 40-6).¹

Physicians who care for patients with syncope are often asked to address the issue of driving risk. Patients who experience syncope while driving pose a risk both to themselves and to others. Although some would argue that all patients with syncope should never drive again because of the theoretical possibility of recurrence, this is an impractical solution that would be ignored by many patients. Factors that should be considered when making a recommendation for a particular patient include (1) the potential for recurrent syncope, (2) the presence and duration of warning symptoms, (3) whether syncope occurs while seated or only when standing, (4) how often and in what capacity the patient drives, and (5) whether any state laws may be applicable.

When considering these issues, physicians should note that acute illnesses, including syncope, are unlikely to cause a motor vehicle accident. A recent study involving 3877 patients with syncope reported that syncope occurred while driving in 380 (9.8%).³¹ The most common cause was reflex syncope (see Table 40-2), which occurred in more than a third. Recurrence of syncope during driving occurred in just 10 patients. Over 8 years of follow-up, the cumulative probability of recurrence while driving was 7%. Importantly, no difference in the total recurrence rate was observed in syncope patients regardless of whether syncope occurred while driving. The American Heart Association and the Canadian Cardiovascular Society have published guidelines concerning this issue. For noncommercial drivers, it is generally recommended that driving be restricted for several months. If the patient remains asymptomatic for several months, driving can then be resumed.

Neurally Mediated Syncope

Because neurally mediated syncope and reflex syncope are so common, treatment options are reviewed (Table 40-7).¹ Treatment of syncope resulting from neurally mediated hypotension begins with a careful history with particular attention focused on identifying precipitating factors, quantifying the degree of salt intake and current

**TABLE 40-7 Treatment of Neurally Mediated and Reflex-Mediated Syncope**

TREATMENT	CLASS	LEVEL OF EVIDENCE
Reassurance and education	I	C
Isometric physical counterpressure maneuvers with a prodrome	I	B
Cardiac pacing should be considered in patients with dominant cardioinhibitory carotid sinus hyposensitivity	IIa	B
Cardiac pacing should be considered with frequent recurrent reflex syncope, age >40 yr, and documented spontaneous cardioinhibitory response during monitoring of recurrent syncope	IIb	B
Midodrine may be indicated in patients with neurally mediated syncope refractory to conservative treatment approaches	IIb	B
Tilt training may be useful for education of patients, but long-term benefit depends on compliance	IIb	B
After alternative treatment has failed, cardiac pacing may be indicated in patients with a tilt-induced cardioinhibitory response; recurrent, frequent, unpredictable syncope; and age >40 yr	IIb	C
Triggers of situations inducing syncope must be avoided as much as possible	III	C
Hypotensive drugs should be discontinued or modified	III	C
Cardiac pacing is not indicated in the absence of a documented cardioinhibitory reflex	III	C
Beta blockers are not indicated	III	A

Modified from Moya A, Sutton R, Ammirati F, et al: Guidelines for the diagnosis and management of syncope (version 2009): The Task Force for the Diagnosis and Management of Syncope of the European Society of Cardiology (ESC). *Eur Heart J* 30:2631, 2009.

medication use, and determining whether the patient has a previous history of peripheral edema, hypertension, asthma, or other conditions that may alter the approach used for treatment. For most patients with neurally mediated syncope, particularly those with infrequent episodes associated with an identifiable precipitant, education plus reassurance is sufficient. Patients should be educated about common precipitating factors such as dehydration, prolonged standing, alcohol, and medications such as diuretics and vasodilators. Patients should also be taught to sit or lie down at the onset of symptoms and to initiate physical counterpressure maneuvers. One recent study reported that a standardized education protocol significantly reduced traumatic injuries and recurrences of syncope.³² In this trial the syncope burden was reduced from 0.35 ± 0.3 at initial evaluation to 0.08 ± 0.02 during follow-up. Volume expansion by salt supplementation is also commonly recommended. Ingestion of approximately 500 mL of water acutely improves orthostatic tolerance to tilt in healthy subjects and may be of value as prophylaxis for syncope in blood donors. The effectiveness of water ingestion alone in the management of patients with recurrent neurally mediated syncope has not been well studied.

A recent important shift in the approach used for the treatment of neurally mediated syncope has resulted from the effectiveness of "physical" measures and maneuvers in the treatment of patients with this condition.^{1,33} Isometric physical counterpressure maneuvers such as leg crossing or handgrip with arm tensing can prevent syncope in many patients with neurally mediated hypotension. The European guidelines on management of syncope identify the following physical measures as class II treatments of neurally mediated syncope: (1) tilt training, (2) head-up tilt sleeping (>10 degrees), (3) isometric leg and arm counterpressure maneuvers, and (4) moderate aerobic and isometric exercise.¹ It has been reported that 2 minutes of an isometric handgrip maneuver initiated at the onset of symptoms during tilt testing rendered two thirds of patients asymptomatic. Other studies have demonstrated that tilt (standing) training is effective in the treatment of neurally mediated syncope. Standing training involves leaning against a wall with the heel 10 inches from the wall for progressively longer periods for 2 to 3 months. Standing time should initially be 5 minutes two times per day with a progressive increase to 40 minutes twice daily. Although the results of nonrandomized studies of standing training have been positive, the results of randomized trials suggest that standing training may have only limited effectiveness.³⁴

In contrast to these effective physical maneuvers, the value of pharmacologic agents is less certain. Medications that are generally relied on to treat neurally mediated syncope include beta blockers,

fludrocortisone, serotonin reuptake inhibitors, and midodrine. Despite the widespread use of these agents, none of these pharmacologic agents has been demonstrated to be effective in multiple large prospective randomized clinical trials. Even though beta blockers were previously considered by many to be first-line therapy, recent studies have reported that the beta blockers metoprolol, propranolol, and nadolol are no more effective than placebo.^{35,36}

Even though pacemakers have also been found to be valuable in the treatment of some patients with neurally mediated syncope in nonrandomized and/or nonblinded clinical trials, blinded randomized clinical trials have shown that pacemakers have no benefit.³⁷ In contrast, one recent randomized trial demonstrated the benefit of implanted pacemakers in a selected population of patients with neurally mediated syncope.³⁸ This double-blind placebo-controlled clinical trial randomly assigned 77 patients 40 years or older with recurrent neurally mediated syncope documented by the use of an implantable loop monitor to be associated with 3 seconds or longer of asystole or a 6-second or greater pause without syncope to dual-chamber pacing with rate drop hysteresis or to sensing only. The 2-year estimated syncope recurrence rate was 57% with pacing off and 25% with pacing on. Overall, the risk for recurrent syncope was reduced by 57% with pacing. Although the 2008 guidelines for device-based therapy state that pacemaker implantation has a IIb indication for the treatment of patients with highly symptomatic, neurally mediated syncope associated with bradycardia documented spontaneously or at the time of tilt-table testing,²² this recent prospective randomized clinical trial provides stronger evidence for pacemaker therapy in patients with neurally mediated syncope who meet the clinical profile of the population of patients enrolled in this trial. The European guidelines on management of syncope provide a somewhat more restrictive recommendation concerning the indications for pacemaker implantation in this setting (see Table 40-7). When considering pacemaker implantation for patients with neurally mediated syncope, pacemakers that provide specialized pacing algorithms are often selected. These include rate drop hysteresis or closed-loop stimulation. Closed-loop stimulation is a form of rate adaptive pacing that responds to myocardial contraction dynamics by measuring variations in right ventricular intracardiac impedance. When an incipient neurally mediated syncopal episode is detected, the pacing rate is increased. Although no prospective randomized clinical trials exist to determine which pacing feature is superior, several recent nonrandomized or retrospective trials suggest that closed-loop stimulation may be preferable.^{38,39} Further research on this evolving approach to the management of neurally mediated syncope is needed.

FUTURE PERSPECTIVES

As the U.S. population ages and the prevalence of cardiac disease increases, it is inevitable that syncope will remain an important clinical problem that physicians of all types will need to be familiar with. We anticipate that over the next 5 years additional studies will confirm the clinical and economic value of syncope evaluation units. This will lead to more widespread use of syncope evaluation units, much like chest pain emergency rooms are now routinely used to evaluate patients with chest pain. It also seems likely that genetic testing will grow in diagnostic importance in the evaluation of patients with syncope. It is notable that clinical genetic testing is now available on a routine clinical basis for many of the inherited cardiac conditions that may be accompanied by syncope, including long-QT syndrome, arrhythmogenic right ventricular dysplasia, and hypertrophic cardiomyopathy. We are also hopeful that new pharmacologic or nonpharmacologic treatments will be developed for the treatment of patients with severe disabling orthostatic hypotension, postural orthostatic tachycardia syndrome, and neurally mediated syncope.

OVERVIEW AND BACKGROUND

The 20th century witnessed a remarkable evolution in concepts concerning the pathogenesis of atherosclerosis. This disease has a venerable history, having left traces in the arteries of Egyptian mummies.¹ Atherosclerosis became epidemic as populations increasingly survived early mortality associated with communicable diseases and malnutrition. Economic development and urbanization promoted habits of poor diet (e.g., a surfeit of saturated fats) and diminished physical activity, which can favor atherogenesis (see Chapters 1, 42, and 45). These environmental factors have spread steadily, such that we face an epidemic of atherosclerosis that reaches far beyond Western societies.

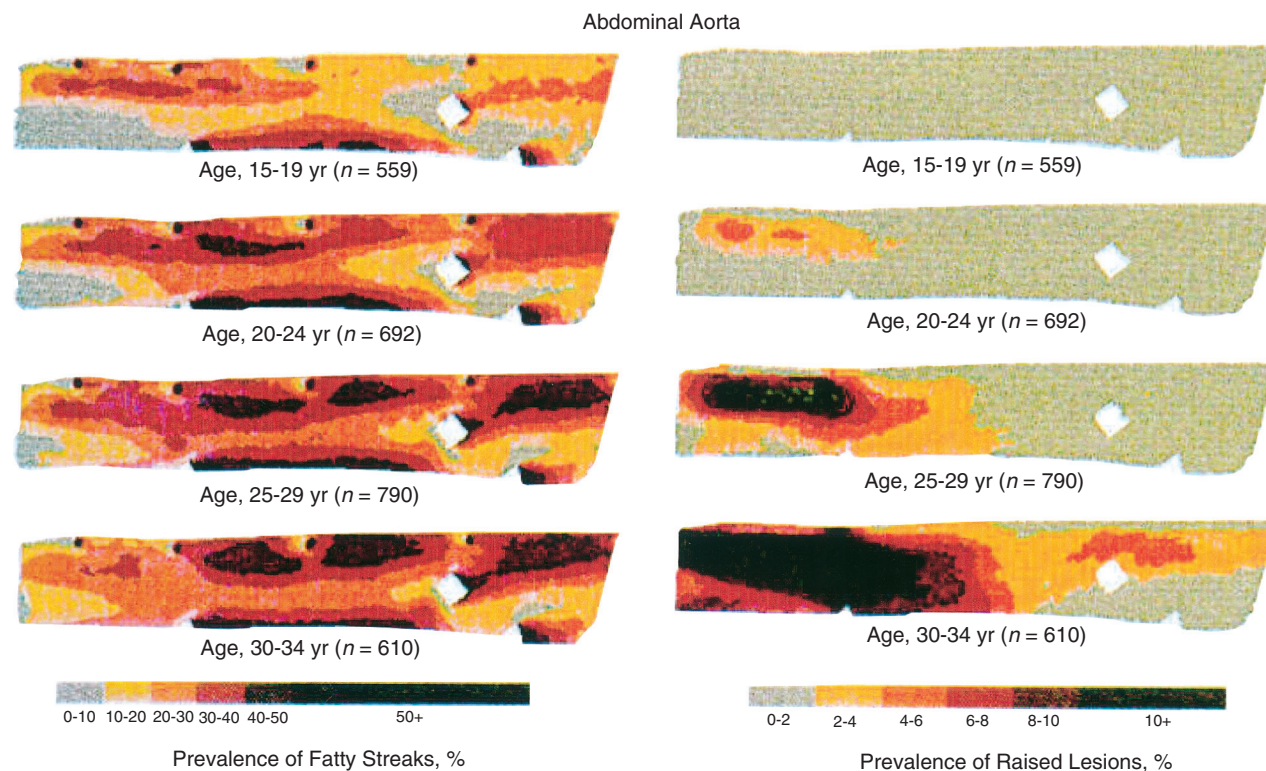

Today, arteries are no longer viewed as inanimate tubes. In the mid-19th century, Rudolf Virchow recognized the participation of cells in atherogenesis. A controversy raged between Virchow, who viewed atherosclerosis as a proliferative disease, and Carl von Rokitansky, who believed that atheroma derived from healing and resorption of thrombi.² Experiments performed in the early part of the 20th century used dietary modulation to produce fatty lesions in the arteries of rabbits and ultimately identified cholesterol as the culprit.³ These observations, followed by the characterization of human lipoprotein particles in the mid-20th century, promoted the insudation of lipids as a cause for atherosclerosis. Elements of all these mechanisms indeed contribute to atherogenesis. This chapter summarizes evidence from human studies, animal experimentation, and in vitro work and presents a synoptic view of atherogenesis from the biologic perspective.

Acquaintance with the vascular biology of atherosclerosis should prove useful to the practitioner. Our daily contact with this common disease lulls us into a complacent belief that we understand it better than we actually do. For example, we have begun to understand why

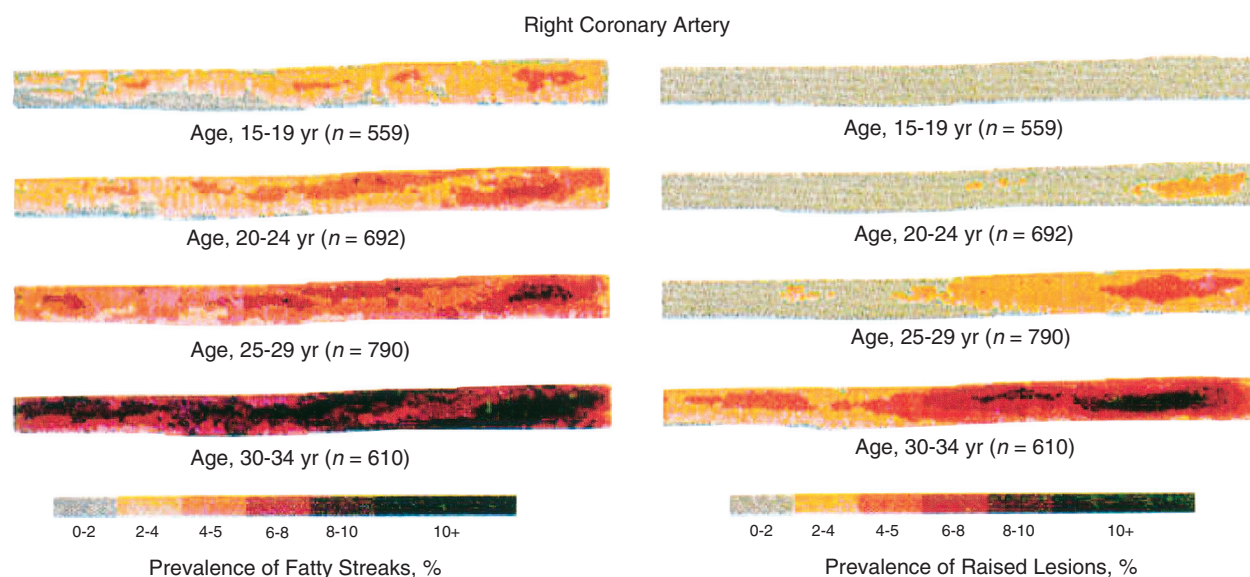

atherosclerosis affects certain regions of the arterial tree preferentially and why its clinical manifestations occur only at certain times. Atherosclerosis can involve both large and mid-size arteries diffusely. Postmortem and intravascular ultrasound clinical studies have revealed widespread intimal thickening in patients with atherosclerosis. Many asymptomatic persons have intimal lesions in their coronary or carotid arteries even in the early decades of life. At the same time, atherosclerosis produces focal stenoses in certain areas of affected vessels much more often than in others. The biologic basis of the predilection of certain sites to develop atherosclerotic lesions has begun to emerge.

Atherosclerosis also displays heterogeneity in time; this disease has both chronic and acute manifestations. Few human diseases have a longer “incubation” period than atherosclerosis, which begins to affect the arteries of many Americans in the second and third decades of life (Fig. 41-1). Indeed, many young Americans have abnormal thickening of the coronary arterial intima; yet typically, symptoms of atherosclerosis emerge only after several decades of delay, characteristically appearing even later in women. Despite this indolent time course and prolonged period of clinical inactivity, the dreaded complications of atheroma—such as myocardial infarction, unstable angina, and stroke—typically occur suddenly and often without warning.

Another poorly understood issue regarding atherogenesis is its role in the narrowing, or stenosis, of some vessels and in the dilation, or ectasia, of others. Traditionally, cardiologists have focused on stenoses in coronary arteries, but atherosclerosis commonly manifests as aneurysms—for example, in the aorta. Even in the life history of a single atherosclerotic lesion, a phase of ectasia known as positive remodeling, or compensatory enlargement, precedes the formation of stenotic lesions. Contemporary vascular biology has begun to shed light on some of these puzzling aspects of atherosclerosis.

STRUCTURE OF THE NORMAL ARTERY

Cell Types Composing the Normal Artery

Endothelial Cells

The endothelial cell (EC) of the arterial intima constitutes the crucial contact surface with blood. Arterial ECs possess many highly regulated mechanisms of capital importance in vascular homeostasis that

often go awry during the pathogenesis of arterial diseases. For example, the EC provides one of the only surfaces, either natural or synthetic, that can maintain blood in a liquid state during protracted contact (Fig. 41-2). This remarkable blood compatibility derives in part from the expression of heparan sulfate proteoglycan molecules on the surface of the EC. These molecules, like heparin, can serve as a cofactor for antithrombin III, causing a conformational change that

FIGURE 41-2 The endothelial thrombotic balance. This diagram depicts the anticoagulant profibrinolytic functions of the endothelial cell (*left*) and certain procoagulant and antifibrinolytic functions (*right*).

allows this inhibitor to bind to and inactivate thrombin. The surface of the EC also contains thrombomodulin, which binds thrombin molecules and can exert antithrombotic properties by activating proteins S and C. Should a thrombus begin to form, the normal EC possesses potent fibrinolytic mechanisms associated with its surface. The EC can produce both tissue- and urokinase-type plasminogen activators. These enzymes—t-PA and u-PA, respectively—catalyze the activation of plasminogen to form plasmin, a fibrinolytic enzyme. (For a complete discussion of the role of endothelium in hemostasis and fibrinolysis, [see Chapter 82](#).)

ECs have a common origin but acquire “bed-specific” characteristics during development. The ECs that form the inner lining of all blood vessels arise during embryogenesis from regions known as the blood islands, located on the embryo’s periphery. Angioblasts, the predecessors of ECs, share this site with the precursors of blood cells. Despite arising from the same site, cells display considerable heterogeneity even during embryologic and early postnatal development. Although ECs presumably derive from a common precursor, the signals they encounter during vessel development differ. As rudimentary blood vessels begin to form, endothelial precursors interact with surrounding cells. The interchange permits spatial and temporal gradients of various stimuli and their receptors on the ECs, leading to this cell type’s heterogeneity in the adult. EC heterogeneity depends on both environmental stimuli and epigenetic features acquired during development.⁴⁻⁶

Cells that make up various compartments of the arterial wall may originate from bone marrow during postnatal life as well as from their traditional embryologic sources. In particular, peripheral blood appears to contain endothelial precursor cells that may help repair areas of endothelial desquamation.⁷ Some experimental evidence has challenged the notion that endothelial progenitor cells (EPCs) populate murine atherosclerotic plaques.⁸

Arterial Smooth Muscle Cells

The second major cell type of the normal artery wall, the smooth muscle cell (SMC), has many important functions in normal vascular homeostasis, as a target of therapies in cardiovascular medicine, and in the pathogenesis of arterial diseases. These cells contract and relax and thus control blood flow through the various arterial beds, generally at the level of the muscular arterioles. In the larger types of arteries involved in atherosclerosis, however, abnormal smooth muscle contraction may cause vasospasm, a complication of atherosclerosis that may aggravate the embarrassment of blood flow. SMCs

synthesize the bulk of the complex arterial extracellular matrix that plays a key role in normal vascular homeostasis and in the formation and complication of atherosclerotic lesions. These cells also can migrate and proliferate, contributing to the formation of intimal hyperplastic lesions, including atherosclerosis and restenosis; stent stenosis after percutaneous intervention; or anastomotic hyperplasia, complicating vein grafts. Death of SMCs may promote destabilization of atheromatous plaques or may favor ectatic remodeling and ultimately aneurysm formation.

In contrast with ECs, thought to derive from a common precursor, SMCs can arise from many sources⁹ ([Fig. 41-3](#)). After ECs form tubes, the rudimentary precursor of blood vessels, they recruit the cells that will become SMCs or pericytes (smooth muscle–like cells associated with microvessels). In the descending aorta and arteries of the lower body, the regional mesoderm serves as the source of smooth muscle precursors. The mesodermal cells in somites give rise to the SMCs that invest much of the distal aorta and its branches. In arteries of the upper body, however, SMCs actually can derive from a completely different germ layer—neurectoderm, rather than mesoderm. Before the neural tube closes, neuroectodermal cells migrate and become the precursors of SMCs in the ascending aorta and some of its branches, including the carotid arteries. SMCs in the coronary arteries derive from mesoderm, but in a special way: The precursors of coronary artery SMCs arise from yet another embryologic source, a structure known as the proepicardial organ.

Lineage analyses indicate that large patches of SMCs in arteries arise as expansions of small clones established early in development.⁹ A small population of precursor cells may reside in the tunica media of normal arteries that give rise to the SMCs that accumulate in injured or atherosclerotic arteries.^{10,11} The heterogeneity of SMCs may have direct clinical implications for explicating several common observations, such as the propensity of certain arteries or regions of arteries to develop atherosclerosis or heightened responses to injury (e.g., the proximal left anterior descending coronary artery), and medial degeneration (e.g., the proximal aorta in Marfan syndrome). Differential responses of SMCs to regulators of extracellular matrix production help explain why the clinical manifestations of systemic defects in fibrillin and elastin characteristically occur locally in the ascending aorta ([see Chapter 57](#)).¹² The plasticity of SMCs may even extend to giving rise to cells with characteristic and functions of mononuclear phagocytes in atherosclerotic plaques.¹³

Layers of the Normal Artery Intima

An understanding of the pathogenesis of atherosclerosis first requires knowledge of the structure and biology of the normal artery and its indigenous cell types. Normal arteries have a well-developed trilaminar structure ([Fig. 41-4](#)). The innermost layer, the tunica intima, is thin at birth in humans and in many nonhuman species. Although it often is depicted as a monolayer of ECs abutting directly on a basal lamina, the structure of the adult human intima is actually much more complex and heterogeneous. The endothelial monolayer resides on a basement membrane containing nonfibrillar collagen types, such as type IV collagen, laminin, fibronectin, and other extracellular matrix molecules. With aging, human arteries develop a more complex intima containing arterial SMCs and fibrillar forms of interstitial collagen (types I and III). SMCs produce these extracellular matrix constituents of the arterial intima. The presence of a more complex intima, known by pathologists as diffuse intimal thickening, characterizes most adult human arteries. Some locales in the arterial tree tend to develop a thicker intima than other regions, even in the absence of atherosclerosis ([Fig. 41-5](#)). For example, the proximal left anterior descending coronary artery often contains a more fully developed intimal cushion of SMCs than that in typical arteries. The diffuse intimal thickening process does not necessarily go hand in hand with lipid accumulation and may occur in persons without substantial burden of atheroma. The internal elastic membrane bounds the tunica intima abluminally and serves as the border between the intimal layer and the underlying tunica media.

FIGURE 41-3 Diversity of the embryologic origin of vascular SMCs. Different colors represent different embryonic sources for SMCs, as indicated in the outlines on the boxed images along the sides of the main drawing. The yellow outline indicates local and systemic contributions by various sources of vascular stem cells. The fate map shows a diverse distribution of SMCs derived from different sources in the aorta and its major branch arteries. With few exceptions, the exact boundaries of SMCs from various sources within the arteries shown are uncertain; accordingly, the boundaries depicted are approximate. In the boxed image at left labeled Somites, note the close proximity of the developing dorsal aorta (ao) to the ventral sclerotome (vs) of the somite (so). The lineage-specific boundaries shown may shift during growth and with aging of vessels. NC = neural crest; nt = neural tube; Rv = right ventricle. (From Majesky MW: *Developmental basis of vascular smooth muscle diversity*. *Arterioscler Thromb Vasc Biol* 27:1248, 2007.)

Tunica Media

The tunica media lies under the intima and internal elastic lamina. The media of elastic arteries such as the aorta has well-developed concentric layers of SMCs, interleaved with layers of elastin-rich extracellular matrix (see Fig. 41-4A). This structure appears well adapted to the storage of the kinetic energy of left ventricular systole by the walls of great arteries. The lamellar structure also certainly contributes to the structural integrity of the arterial trunks. The media of smaller muscular arteries usually has a less stereotyped organization (see Fig. 41-4B). SMCs in these smaller arteries generally embed in the surrounding matrix in a more continuous than lamellar array. The SMCs in normal arteries seldom proliferate. Indeed, rates of both cell division and cell death are low under usual circumstances. In the normal artery, a state of homeostasis of extracellular matrix also typically prevails. Because extracellular matrix neither accumulates nor atrophies, rates of arterial matrix synthesis and dissolution usually balance each other. The external elastic lamina bounds the tunica media abluminally, forming the border with the adventitial layer.

Adventitia

The adventitia of arteries typically has received little attention, although appreciation of its potential roles in arterial homeostasis and pathology has increased. The adventitia contains collagen fibrils in a looser array than that usually encountered in the intima. Vasa vasorum and nerve endings localize in this outermost layer of the arterial wall. The cellular population in the adventitia is sparser than in other arterial layers. Cells encountered in this layer include

fibroblasts and mast cells (see Fig. 41-4). Emerging evidence suggests a role for mast cells in atheroma and aneurysm formation in animal models, but their importance in humans remains speculative.^{14,15}

ATHEROSCLEROSIS INITIATION

Extracellular Lipid Accumulation

The first steps in human atherogenesis remain largely conjectural, but the integration of observations of tissues obtained from young humans with the results of experimental studies of atherogenesis in animals provides hints in this regard. On initiation of an atherogenic diet, typically rich in cholesterol and saturated fat, small lipoprotein particles accumulate in the intima (Fig. 41-6, steps 1 and 2). These lipoprotein particles appear to decorate the proteoglycan of the arterial intima and tend to coalesce into aggregates (Fig. 41-7). Detailed kinetic studies of labeled lipoprotein particles indicate that a prolonged residence time characterizes sites of early lesion formation in rabbits. The binding of lipoproteins to proteoglycan in the intima leads to their capture and retention, accounting for their prolonged residence time. Lipoprotein particles bound to proteoglycan have increased susceptibility to oxidative or other chemical modifications, considered by many to contribute to the pathogenesis of early atherosclerosis (step 2 in Fig. 41-6). Other studies suggest that permeability of the endothelial monolayer increases at sites of lesion predilection to low-density lipoprotein (LDL). Contributors to oxidative stress in the nascent atheroma could include reduced nicotinamide adenine dinucleotide/

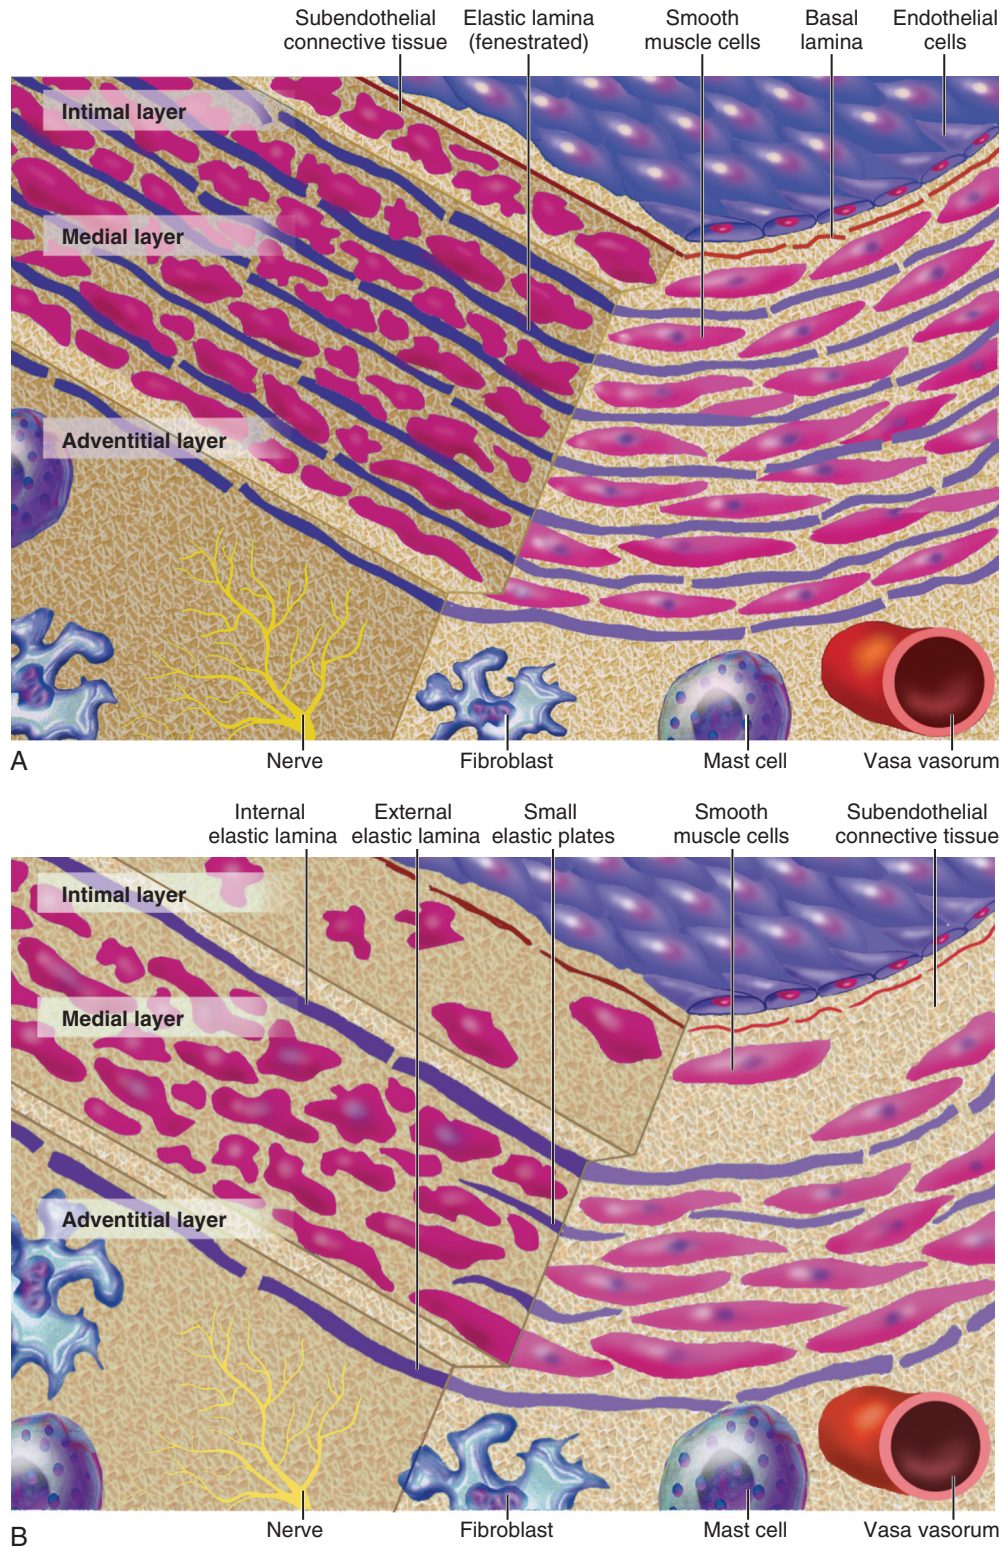

FIGURE 41-4 The structures of normal arteries. **A**, Elastic artery. Note the concentric laminae of elastic tissue that form sandwiches with successive layers of SMCs. Each level of the elastic arterial tree has a characteristic number of elastic laminae. **B**, Muscular artery. In the muscular artery, the SMCs are surrounded by a collagenous matrix but lack the concentric rings of the well-organized elastic tissue characteristic of larger arteries.

nicotinamide adenine dinucleotide phosphate (NADH/NADPH) oxidases expressed by vascular cells, lipoxigenases expressed by infiltrating leukocytes, or the enzyme myeloperoxidase.

Leukocyte Recruitment and Retention

Another hallmark of atherogenesis, leukocyte recruitment and accumulation (step 4 in Fig. 41-6), also occurs early in lesion generation

(Fig. 41-8). The normal EC generally resists adhesive interactions with leukocytes. Even in inflamed tissues, most recruitment and trafficking of leukocytes occurs in postcapillary venules and not in arteries. Very soon after initiation of hypercholesterolemia, however, leukocytes adhere to the endothelium and move between EC junctions, or even penetrate through ECs (transcytosis) to enter the intima, where they begin to accumulate lipids and become foam cells¹⁶ (step

5 in Fig. 41-6) (see Fig. 41-8). In addition to the monocyte, T lymphocytes also tend to accumulate in early human and animal atherosclerotic lesions. The expression of certain leukocyte adhesion molecules on the surface of the EC regulates the adherence of monocytes and T cells to the endothelium.¹⁷ Several categories of leukocyte adhesion molecules exist. Members of the immunoglobulin superfamily include structures such as vascular cell adhesion molecule 1 (VCAM-1), or CD106. This adhesion molecule is of particular interest in the context of early atherogenesis because it interacts with an integrin (very late antigen 4 [VLA-4]) characteristically expressed by only those classes of leukocytes that accumulate in nascent atheroma—monocytes and T cells. Moreover, experimental studies

have shown expression of VCAM-1 on ECs overlying very early atherosclerotic lesions. Other members of the immunoglobulin superfamily of leukocyte adhesion molecules include intercellular adhesion molecule 1 (ICAM-1). This molecule is more promiscuous, both in the types of leukocytes it binds and in its wide and constitutive expression at low levels by ECs in many parts of the circulation.

Selectins constitute the other broad category of leukocyte adhesion molecules. The prototypical selectin, E-selectin or CD62E (E stands for “endothelial,” the cell type that selectively expresses this particular family member), probably has little to do with early

FIGURE 41-5 An intimal cushion shown in cross section through the internal carotid artery of a 10-week-old male infant. Areas in which intimal cushions form in early life tend to develop atheromas more commonly in later years. Bar = 0.5 mm. (From Weniger WJ, Muller GB, Reiter C, et al: *Intimal hyperplasia of the infant parasellar carotid artery: A potential developmental factor in atherosclerosis and SIDS*. *Circ Res* 85:970, 1999.)

FIGURE 41-7 Scanning electron micrograph of a freeze-etch preparation of rabbit aorta that received an intravenous injection of human low-density lipoprotein (LDL). Round LDL particles decorate the strands of proteoglycan found in the sub-endothelial region of the intima. By binding LDL particles, proteoglycan molecules can retard their traversal of the intima and promote their accumulation. Proteoglycan-associated LDL appears particularly susceptible to oxidative modification. Accumulation of extracellular lipoprotein particles is one of the first morphologic changes noted after initiation of an atherogenic diet in experimental animals. (From Nievelstein PF, Fogelman AM, Mottino G, Frank JS: *Lipid accumulation in rabbit aortic intima 2 hours after bolus infusion of low density lipoprotein. A deep-etch and immunolocalization study of ultrarapidly frozen tissue*. *Arterioscler Thromb* 11:1795, 1991.)

FIGURE 41-6 Schematic of the evolution of the atherosclerotic plaque. 1, Accumulation of lipoprotein particles in the intima (yellow spheres). The modification of these lipoproteins is depicted by the darker color. Modifications include oxidation and glycation. 2, Oxidative stress, including products found in modified lipoproteins, can induce local cytokine elaboration (green spheres). 3, The cytokines thus induced increase expression of adhesion molecules (blue stalks on endothelial surface) for leukocytes that cause their attachment and chemoattractant molecules that direct their migration into the intima. 4, Blood monocytes, on entering the artery wall in response to chemoattractant cytokines such as monocyte chemoattractant protein 1 (MCP-1), encounter stimuli such as macrophage colony-stimulating factor that can augment their expression of scavenger receptors. 5, Scavenger receptors mediate the uptake of modified lipoprotein particles and promote the development of foam cells. Macrophage foam cells are a source of mediators, such as additional cytokines and effector molecules such as hypochlorous acid, superoxide anion (O_2^-), and matrix metalloproteinases. 6, SMCs migrate into the intima from the media. 7, SMCs can then divide and elaborate extracellular matrix, promoting extracellular matrix accumulation in the growing atherosclerotic plaque. In this manner, the fatty streak can evolve into a fibrofatty lesion. 8, In later stages, calcification can occur (not depicted) and fibrosis continues, sometimes accompanied by SMC death (including programmed cell death or apoptosis), yielding a relatively acellular fibrous capsule surrounding a lipid-rich core that also may contain dying or dead cells and their detritus. IL = interleukin; LDL = low-density lipoprotein.

FIGURE 41-8 Electron microscopy of leukocyte interactions with the artery wall in hypercholesterolemic nonhuman primates. **A, B**, Scanning electron micrographs demonstrate the adhesion of mononuclear phagocytes to the intact endothelium 12 days after initiation of a hypercholesterolemic diet in monkeys. **C, D**, Transmission electron micrographs. Note the abundant interdigitations and intimate association of the monocyte with the endothelium in **C**. In **D**, a monocyte appears to come between two endothelial cells to enter the intima. (From Faggitto A, Ross R, Harker L: *Studies of hypercholesterolemia in the nonhuman primate. I. Changes that lead to fatty streak formation*. *Arteriosclerosis* 4:323, 1984.)

atherogenesis. E-selectin preferentially recruits polymorphonuclear leukocytes, a cell type seldom found in early atheromata (but an essential protagonist in acute inflammation and host defenses against bacterial pathogens). Moreover, ECs overlying atheroma do not express high levels of this adhesion molecule. Other members of this family, including P-selectin, or CD62P (P stands for “platelet,” the original source of this adhesion molecule), may play a greater role in leukocyte recruitment in atheroma, because ECs overlying human atheroma express this adhesion molecule. Selectins tend to promote saltatory or rolling locomotion of leukocytes over the endothelium. Adhesion molecules belonging to the immunoglobulin superfamily tend to promote tighter adhesive interactions and immobilization of leukocytes. Studies in genetically altered mice have proven roles for VCAM-1 and P-selectin (including both platelet-derived and endothelium-derived P-selectin) in experimental atherosclerosis. Increasing evidence supports the accumulation in atheromas of distinct subtypes of mononuclear phagocytes.^{16,18-21} The functional consequences of this heterogeneity of macrophage populations in plaques require further study, especially in humans. In mice, a particularly proinflammatory subset of monocytes accumulates in the spleen and peripheral blood in response to hypercholesterolemia and preferentially populates nascent atheroma.²¹

Once adherent to the endothelium, leukocytes must receive a signal to penetrate the endothelial monolayer and enter the arterial wall (step 4 in Fig. 41-6). The current concept of directed migration of leukocytes involves the action of protein molecules known as chemoattractant cytokines or chemokines.^{16,22} Among the many chemokines implicated in atherogenesis, two are of particular interest in recruiting the mononuclear cells characteristic of the early atheroma. One such molecule, known as monocyte chemoattractant protein 1

(MCP-1), or CCL2, is produced by the endothelium in response to oxidized lipoprotein and other stimuli. Cells intrinsic to the normal artery, including ECs and SMCs, can produce this chemokine when stimulated by inflammatory mediators, as do many other cell types. MCP-1 selectively promotes the directed migration, or chemotaxis, of monocytes. Atherosclerosis-prone mice lacking MCP-1 or its receptor CCR2 exhibit delayed and attenuated lesion formation. Human atherosclerotic lesions express increased levels of MCP-1 compared with uninvolved vessels. In mice, the CCL2/CCR2 dyad recruits preferentially the proinflammatory monocyte subset.²¹ Fractalkine, a unique cell surface-bound chemokine, also appears to contribute to atherogenesis and typically interacts with the less inflammatory subset of monocytes.²³ Another group of chemoattractant cytokines may heighten lymphocyte accumulation in plaques as well: Atheromas express a trio of lymphocyte-selective chemokines (IP-10 or CXCL10, I-TAC or CXCL11, and MIG or CXCL9). Interferon- γ , a cytokine known to be present in atheromatous plaques, induces the genes encoding this family of T cell chemoattractants. The accumulation of monocytes in plaques depends not only on their recruitment, but also on their retention.²⁴ Recent work has implicated netrin-1 interacting with its receptor UNC5b (both induced by hypoxia) as a protein that retards macrophages from exiting plaques.²⁵⁻²⁷

Focality of Lesion Formation

The spatial heterogeneity of atherosclerosis is challenging to explain in mechanistic terms. Equal concentrations of bloodborne risk factors such as lipoproteins bathe the endothelium throughout the vasculature. It is difficult to envisage how injury due to inhalation of cigarette smoke could produce any local rather than global effect on arteries, yet stenoses due to atheromas typically form focally. Some researchers have invoked a multicentric origin hypothesis of atherogenesis, positing that atheromas arise as benign leiomyomas of the artery wall. The monotypia of various molecular markers in individual atheromas supports this monoclonal hypothesis of atherogenesis.⁹ The location of sites of lesion predilection at proximal portions of arteries after branch points or bifurcations at flow dividers, however, suggests a hydrodynamic basis for early lesion development. Arteries without many branches (e.g., the internal mammary and radial arteries) tend not to develop atherosclerosis.

Two concepts can aid in understanding how local flow disturbances might render certain foci sites of lesion predilection. Locally disturbed flow could induce alterations that promote the steps of early atherogenesis. Alternatively, the laminar flow that usually prevails at sites that do not tend to develop early lesions may elicit antiatherogenic homeostatic mechanisms (atheroprotective functions).²⁸ The EC experiences the laminar shear stress of normal flow and the disturbed flow (usually yielding decreased shear stress) at sites of predilection.²⁹ Multiple mechanotransduction mechanisms operate to signal the local shear stress environment to ECs. For example, these cells have cilia on their luminal surface and adhesion receptors in their lateral cell membrane that can sense tension, transmit forces to the cortical cytoskeleton, and potentially regulate ion channels or G protein-coupled receptors that signal changes in gene expression (Fig. 41-9A).^{29,30} In vitro data suggest that laminar shear stress can augment the expression of genes that may protect against atherosclerosis, including forms of the enzymes superoxide dismutase and nitric oxide synthase.²⁸ Superoxide dismutase can reduce oxidative stress by catabolizing the reactive and injurious superoxide anion. Endothelial nitric oxide synthase produces the

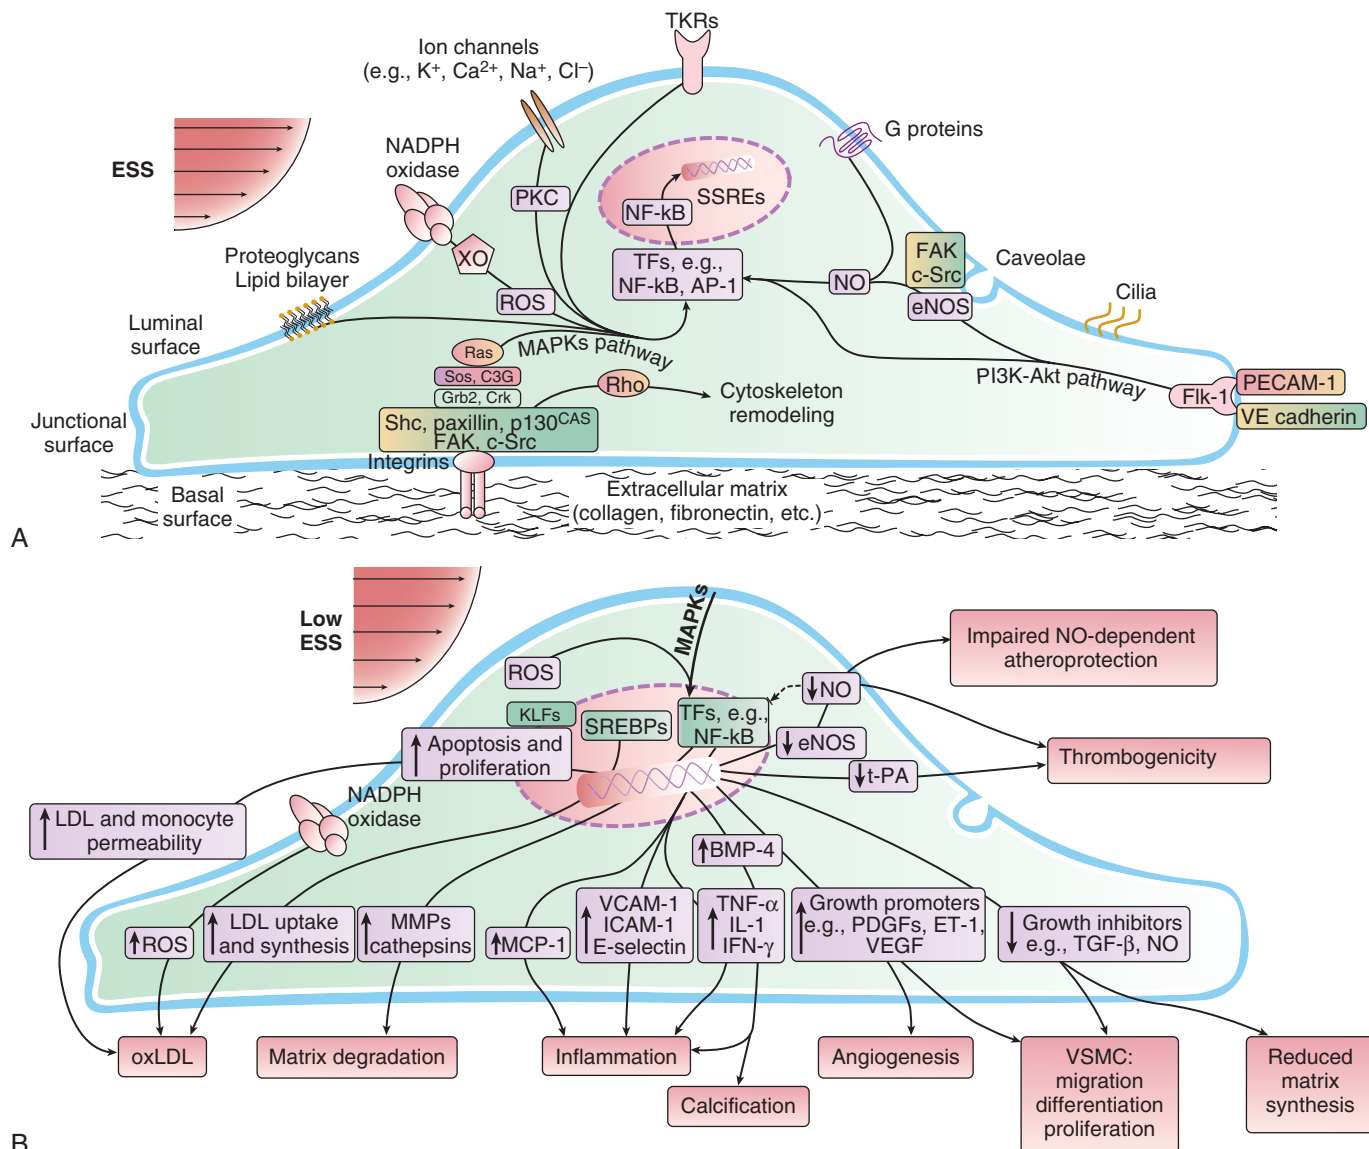

FIGURE 41-9 Mechanotransduction of endothelial shear stress (ESS). **A**, Interaction of ESS with mechanosensors activates intracellular signaling cascades. **B**, Low ESS promotes inflammation, degradation of the extracellular matrix, and other characteristics associated with plaques that cause the thrombotic complications of atherosclerosis. (Modified from Chatzizisis YS, Coskun AU, Jonas M, et al: Role of endothelial shear stress in the natural history of coronary atherosclerosis and vascular remodeling: molecular, cellular, and vascular behavior. *J Am Coll Cardiol* 49:2379, 2007; and Hahn C, Schwartz MA: Mechanotransduction in vascular physiology and atherogenesis. *Nat Rev Mol Cell Biol* 10:53, 2009.)

well-known endogenous vasodilator nitric oxide. Beyond its vasodilating actions, however, nitric oxide can resist inflammatory activation of endothelial functions, such as expression of the adhesion molecule VCAM-1. Nitric oxide appears to exert this anti-inflammatory action at the level of gene expression by interfering with the transcriptional regulator nuclear factor κ B (NF- κ B). Nitric oxide increases the production of I κ B α , an intracellular inhibitor of this important transcription factor. NF- κ B regulates numerous genes involved in inflammatory responses in general, and in atherogenesis in particular.

Studies also implicate transcription factors, notably Krüppel-like factor 2 (KLF2), as important regulators of endothelial anti-inflammatory properties.³¹ KLF2 can induce endothelial nitric oxide synthase expression and also inhibits NF- κ B function by sequestering cofactors needed to boost NF- κ B transcriptional activity, resulting in inhibition of the expression of the cassette of NF- κ B-dependent genes involved in the inflammatory pathways that operate during

atherogenesis (Fig. 41-9B). Mice with partial disruption of KLF2 signaling have increased atherosclerosis.³² Thus several atheroprotective mechanisms operate such that under usual conditions of laminar shear stress in normal arteries, the endothelium tonically expresses locally acting anti-inflammatory function. Studies in intact pigs and humans show that sites of low shear stress in coronary arteries associate with the development of characteristics of plaques associated with rupture and thrombosis.^{29,33-35}

Intracellular Lipid Accumulation: Foam Cell Formation

The monocyte, once recruited to the arterial intima, can imbibe lipid and become a foam cell or lipid-laden macrophage (step 5 in Fig. 41-6). Although most cells can express the classic cell surface receptor for LDL, that receptor does not mediate foam cell accumulation

(see Chapter 45). This is evident clinically, because tendinous xanthomas filled with foamy macrophages still develop in patients lacking functional LDL receptors (familial hypercholesterolemia homozygotes). The LDL receptor does not mediate foam cell formation, because of its exquisite regulation by cholesterol. As soon as a cell collects enough cholesterol for its metabolic needs from LDL capture, an elegant transcriptional control mechanism quenches expression of the receptor (see Chapter 45).

Instead of the classic LDL receptor, various molecules known as scavenger receptors appear to mediate the excessive lipid uptake characteristic of foam cell formation. These surface molecules, belonging to several families, bind modified rather than native lipoproteins and participate in their internalization.³⁶ Atherosclerosis-prone mice with mutations that delete functional scavenger receptor-A exhibit less exuberant fatty lesion formation than that seen in mice with functional scavenger receptor-A molecules. Because scavenger receptors have functions such as recognition of apoptotic cells and modified lipoproteins, they are likely to have complex roles during different stages of atherosclerosis. Other receptors that bind modified lipoprotein and that may participate in foam cell formation include CD36 and macrophage, the latter exhibiting preferential binding specificity for oxidized forms of LDL. (See Chapter 45 for a table of scavenger receptors.)

Once macrophages have taken up residence in the intima and become foam cells, they can replicate. In experimental atherosclerosis in mice, monocyte recruitment from blood initially populates the nascent lesion with mononuclear phagocytes, but local proliferation predominates in the established lesion.³⁷ The factors that trigger macrophage cell division in the atherosclerotic plaque probably include hematopoietic growth factors such as macrophage colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and interleukin-3. These comitogens and survival factors for mononuclear phagocytes exist in human and experimental atheromatous lesions. Up to this point in the development of the nascent atheroma, the lesion consists primarily of lipid-engorged macrophages. Complex features such as fibrosis, thrombosis, and calcification do not characterize the fatty streak, the precursor lesion of the complex atheroma. Several lines of evidence suggest that such fatty streaks can regress, at least to some extent. The relative contributions of reduced recruitment, death of

cells within lesions, and egress of cells to reduced accumulation on mononuclear phagocytes in atheromata under conditions of lipid lowering remain controversial.

EVOLUTION OF ATHEROMA

Innate and Adaptive Immunity: Mechanisms of Inflammation in Atherogenesis

During the past decade, the convergence of basic and clinical evidence has demonstrated a fundamental role for inflammation in atherogenesis (see also Chapter 42).³⁸⁻⁴⁰ The macrophage foam cells recruited to the artery wall early in this process serve not only as a reservoir for excess lipid; in the established atherosclerotic lesion, these cells are a rich source of proinflammatory mediators, including proteins such as cytokines and chemokines, and various eicosanoids and other lipid mediators. These phagocytic cells also can elaborate large quantities of oxidant species, such as superoxide anion or hypochlorous acid, in the milieu of the atherosclerotic plaque. This ensemble of inflammatory mediators can promote inflammation in the plaque and thereby contribute to the progression of lesions. The term *innate immunity* describes this type of amplification of the inflammatory response that does not depend on antigenic stimulation (Fig. 41-10).

In addition to innate immunity, mounting evidence supports a prominent role for antigen-specific or adaptive immunity in plaque progression.^{40,41} In addition to the mononuclear phagocytes, dendritic cells in atherosclerotic lesions can present antigens to the T cells that constitute an important minority of the leukocytes in atherosclerotic lesions. Candidate antigens for stimulation of this adaptive immune response include modified or native lipoproteins, heat shock proteins, beta₂-glycoprotein Ib, and infectious agents.⁴²⁻⁴⁴ The antigen-presenting cells (macrophages, dendritic cells, or ECs) allow the antigen to interact with T cells in a manner that triggers their activation. The activated T cells then can secrete copious quantities of cytokines that can modulate atherogenesis.

The helper T cells (bearing CD4) fall into two general categories. Cells of the T helper 1 subtype elaborate proinflammatory cytokines such as interferon- γ , lymphotoxin, CD40 ligand, and tumor necrosis factor- α . This panel of Th1 cytokines can in turn activate vascular wall cells and orchestrate alterations in plaque biology that can lead

FIGURE 41-10 Innate and adaptive immunity in atherosclerosis. A diagram of the pathways of innate (left) and adaptive (right) immunity operating during atherogenesis. BAFF = B-cell activating factor; IFN- γ = interferon- γ ; IL = interleukin; MΦ = macrophage; Th = T helper; TGF- β = transforming growth factor beta. (After Hansson G, Libby P, Schoenbeck U, Yan ZQ: Innate and adaptive immunity in the pathogenesis of atherosclerosis. *Circ Res* 91:281, 2002.)

to plaque destabilization and heightened thrombogenicity. On the other hand, helper T cells slanted toward the production of Th2 cytokines, such as interleukin-10, can inhibit inflammation in the context of atherogenesis.⁴⁵ Cytolytic T cells (bearing CD8) can express Fas ligand and other cytotoxic factors that can promote cytolysis and apoptosis of target cells, including SMCs, ECs, and macrophages. The death of all three of these cell types can occur in the atherosclerotic lesion and may contribute to plaque progression and complication. Regulatory T cells (Tregs) can elaborate transforming growth factor- β (TGF- β) and interleukin-10. Treg lymphocytes bear the markers CD4 and CD25. Both TGF- β and interleukin-10 can exert anti-inflammatory effects. Several experimental preparations suggest an antiatherosclerotic function of Tregs in vivo.^{41,46} The role of B cells and antibody in atherosclerosis remains incompletely explored. Humoral immunity may have either atheroprotective or atherogenic properties, depending on the circumstances.⁴⁷ B1 cells that produce natural antibodies, many of which recognize oxidatively modified LDL, can protect against experimental atherosclerosis. B2 cells aggravate atherosclerosis in mice by promoting proinflammatory cytokine production.⁴⁰ This observation has incited interest in immunotherapy to mitigate atherosclerosis.^{40,48}

Smooth Muscle Cell Migration and Proliferation

Whereas the early events in atheroma initiation involve primarily altered endothelial function and recruitment and accumulation of leukocytes, the subsequent evolution of atheroma into more complex plaques also involves SMCs (steps 6 and 7 in Fig. 41-6). SMCs in the normal arterial tunica media differ considerably from those in the intima of an evolving atheroma.⁹⁻¹¹ Some SMCs probably arrive in the arterial intima early in life; others accumulate in advancing atheroma after recruitment from the underlying media into the intima or arise from blood-borne precursors. Experimental evidence in mice has challenged the concept of recruitment of bloodborne SMCs into plaques, and other recent data suggest resident vascular stem cells as a precursor of intimal SMCs in injured or atheromatous arteries.^{10,11,49,50}

SMCs in the atherosclerotic intima appear to exhibit a less mature phenotype than that for the quiescent SMCs in the normal arterial medial layer. Instead of expressing primarily isoforms of smooth muscle myosin characteristic of adult SMCs, those in the intima have higher levels of the embryonic isoform of smooth muscle myosin. Thus SMCs in the intima seem to recapitulate an embryonic phenotype. These intimal SMCs in atheroma appear to be morphologically distinct as well. They contain more rough endoplasmic reticulum and fewer contractile fibers than do normal medial SMCs.

Although replication of SMCs in the steady state appears infrequent in mature human atheroma, bursts of SMC replication may occur during the life history of a given atheromatous lesion. For example, and as discussed in considerable detail later in this chapter, episodes of plaque disruption with thrombosis may expose SMCs to potent mitogens, including the coagulation factor thrombin itself. Thus accumulation of SMCs during atherosclerosis and growth of the intima may not occur in a continuous and linear fashion. Rather, "crises" may punctuate the history of an atheroma, during which bursts of smooth muscle activity may occur (Fig. 41-11).

Smooth Muscle Cell Death During Atherogenesis

In addition to SMC replication, death of these cells also may participate in complication of the atherosclerotic plaque (step 8 in Fig.

FIGURE 41-11 The time course of atherosclerosis. **Left**, Traditional teaching held that atheroma formation followed an inexorably progressive course with age, as depicted by the smooth upward curve. **Right**, Current thinking suggests an alternative model, a step function rather than a monotonically upward course of lesion evolution in time, as depicted by the serpentine curve. According to this latter model, "crises" can punctuate periods of relative quiescence during the life history of a lesion. Such crises might follow an episode of plaque disruption, with mural thrombosis, and healing, yielding a spurt in smooth muscle proliferation and matrix deposition. Intraplaque hemorrhage from rupture of a friable microvessel might produce a similar scenario. Such episodes usually are clinically inapparent. Extravascular events, such as an intercurrent infection with systemic cytokinemia or endotoxemia, could elicit an "echo" at the level of the artery wall, evoking a round of local cytokine gene expression by "professional" inflammatory leukocytes resident in the lesion. The episodic model of plaque progression fits better with human angiographic data than does the traditional model of continuous function.

41-6).^{51,52} Some SMCs in advanced human atheroma exhibit fragmentation of their nuclear DNA that is characteristic of programmed cell death or apoptosis. Apoptosis may occur in response to inflammatory cytokines present in the evolving atheroma. In addition to soluble cytokines that may trigger programmed cell death, T cells in atheroma may participate in eliminating some SMCs. In particular, certain T cell populations known to accumulate in plaques can express Fas ligand on their surface. Fas ligand can engage Fas on the surface of SMCs and, in conjunction with soluble proinflammatory cytokines, lead to SMC death.⁵¹

Thus SMC accumulation in the growing atherosclerotic plaque probably results from a tug-of-war between cell replication and cell death.^{51,52} Contemporary cell and molecular biologic research has identified candidates for mediation of both the replication and the attrition of SMCs, a concept that originated from Virchow's careful morphologic observations made in the mid-19th century. Referring to the SMCs in the intima, Virchow noted that early atherogenesis involves a "multiplication of their nuclei" but also noted that cells in lesions can "hurry on to their own destruction."

Arterial Extracellular Matrix

Extracellular matrix, rather than cells themselves, makes up much of the volume of an advanced atherosclerotic plaque. Accordingly, extracellular constituents of plaque also require consideration. The major extracellular matrix macromolecules that accumulate in atheroma include interstitial collagens (types I and III) and proteoglycans such as versican, biglycan, aggrecan, and decorin. Elastin fibers also may accumulate in atherosclerotic plaques. Arterial SMCs produce these matrix molecules in disease, just as they do during development and maintenance of the normal artery (step 7 in Fig. 41-6). Stimuli for excessive collagen production by SMCs include platelet-derived growth factor (PDGF) and TGF- β , a constituent of platelet granules, and a product of many cell types found in lesions, including Tregs.

Much as with the accumulation of SMCs, extracellular matrix secretion also depends on a balance, as noted earlier. In this case, the counterpoise to biosynthesis of the extracellular matrix molecules is breakdown catalyzed in part by catabolic enzymes, notably the matrix metalloproteinases (MMPs). Dissolution of extracellular

matrix macromolecules undoubtedly contributes to the migration of SMCs as they penetrate into the intima from the media through a dense extracellular matrix, traversing the elastin-rich internal elastic lamina.

Extracellular matrix breakdown also likely plays a role in arterial remodeling that accompanies lesion growth. During the early life of an atheromatous lesion, plaques grow outwardly, in an abluminal direction, rather than inwardly, in a way that would lead to luminal stenosis. This outward growth of the intima leads to an increase in the caliber of the entire artery. This so-called positive remodeling or compensatory enlargement must involve turnover of extracellular matrix molecules to accommodate the circumferential growth of the artery. Luminal stenosis tends to occur only after the plaque burden exceeds some 40% of the cross-sectional area of the artery.

Angiogenesis in Plaques

Atherosclerotic plaques develop their own microcirculation as they grow, because of endothelial migration and replication. Histologic examination with appropriate markers for ECs reveals a rich neovascularization in evolving plaques. These microvessels probably form in response to angiogenic peptides overexpressed in atheroma. These angiogenesis factors include vascular endothelial growth factor (VEGF) forms of fibroblast growth factors, placental growth factor (PIGF), and oncostatin M.

These microvessels within plaques probably have considerable functional significance. For example, the abundant microvessels in plaques provide a relatively large surface area for the trafficking of leukocytes, which could include both entry and exit of leukocytes. Indeed, in the advanced human atherosclerotic plaque, microvascular endothelium displays mononuclear cell-selective adhesion molecules such as VCAM-1 much more prominently than does the macrovascular endothelium overlying the plaque. The microvascularization of plaques also may allow growth of the plaque, overcoming diffusion limitations on oxygen and nutrient supply, in analogy with the concept of tumor angiogenic factors and growth of malignant lesions.⁵³ Consistent with this view, administration of inhibitors of angiogenesis to mice with experimentally induced atherosclerosis limits lesion expansion. Finally, the plaque microvessels may be friable and prone to rupture like the neovessels in the diabetic retina. Hemorrhage and thrombosis in situ could promote a local round of SMC proliferation and matrix accumulation in the area immediately adjacent to the microvascular disruption (Fig. 41-12). This scenario illustrates a special case of one of the crises described earlier in the evolution of the atheromatous plaque (see Fig. 41-11). Attempts to

augment myocardial perfusion by enhancing new vessel growth through the transfer of angiogenic proteins or their genes may have adverse effects on lesion growth or induce clinical complications of atheroma by these mechanisms.

Plaque Mineralization

Plaques often develop areas of calcification as they evolve. Indeed, Virchow recognized morphologic features of bone formation in atherosclerotic plaques in early microscopic descriptions of atherosclerosis. Understanding of the mechanism of mineralization during the evolution of atherosclerotic plaques has advanced. Some subpopulations of SMCs may foster calcification by enhanced secretion of cytokines such as bone morphogenetic proteins, homologues of TGF- β .⁵⁴ Atheroma calcification shares many mechanisms with bone formation. Receptor activator of NF- κ B ligand (RANKL), a member of the tumor necrosis factor family, appears to promote SMC mineral formation through a bone morphogenetic protein 4 (BNP4)-dependent pathway. Osteoprotegerin can antagonize plaque mineralization by inhibiting RANKL signaling. Genetic absence of osteoprotegerin augments calcification of mouse atheromas, and administration of exogenous osteoprotegerin limits it.^{54,55} The transcription factor Runx-2, activated by inflammatory mediators and oxidative stress among other stimuli, can promote SMC mineral formation by activating AKT (i.e., protein kinase B).^{56,57} Markers of inflammation colocalize with foci of mineralization in nascent mouse atheromata.⁵⁶ Microparticles elaborated by macrophages may provide niduses for plaque calcification, yielding another link between inflammatory cells and cardiovascular calcification.⁵⁸

COMPLICATION OF ATHEROSCLEROSIS

Arterial Stenoses and Their Clinical Implications

The previous sections have discussed the initiation and evolution of the atherosclerotic plaque. These phases of the atherosclerotic process generally last many years, during which the affected person often has no symptoms. After the plaque burden exceeds the capacity of the artery to remodel outward, encroachment on the arterial lumen begins. During the chronic asymptomatic or stable phase of lesion evolution, growth probably occurs discontinuously, with periods of relative quiescence punctuated by episodes of rapid progression (see Fig. 41-11). Human angiographic studies support this

FIGURE 41-12 Intraplaque hemorrhage surrounding neovessels in an atheroma. **A, B**, A typical human atherosclerotic plaque, stained for von Willebrand factor (VWF) (**A**) and for iron by Prussian blue (**B**). The von Willebrand factor stains the endothelial cells that line the microvascular channels and lakes. Note the extravasated von Willebrand factor, which colocalizes with iron deposition, indicating hemosiderin deposition consistent with an intraplaque hemorrhage. (After Brogi E, Winkles JA, Underwood R, et al: Distinct patterns of expression of fibroblast growth factors and their receptors in human atheroma and non-atherosclerotic arteries: Association of acidic FGF with plaque microvessels and macrophages. *J Clin Invest* 92:2408, 1993.)

discontinuous growth of coronary artery stenoses. Eventually, the stenoses may progress to a degree that impedes blood flow through the artery. Lesions that produce stenoses of greater than 60% can cause flow limitations under conditions of increased demand. This type of athero-occlusive disease commonly produces chronic stable angina pectoris or intermittent claudication on increased demand. Thus the symptomatic phase of atherosclerosis usually begins many decades after lesion initiation.

In many cases of myocardial infarction, however, no history of previous stable angina heralds the acute event. Several kinds of imaging data suggest that many myocardial infarctions result not from high-grade stenoses but from lesions that do not limit flow. Acute coronary syndromes often result from thrombi that form as a consequence of disruption of plaques that do not produce a critical stenosis.⁵⁹

These findings do not imply that small atheromas cause most myocardial infarctions. Indeed, culprit lesions of acute myocardial infarction may be sizable; but they may not produce a critical luminal narrowing because of compensatory enlargement. Of course, critical stenoses do cause myocardial infarctions, and high-grade stenoses are more likely to cause acute myocardial infarction than are nonocclusive lesions; yet because the noncritical stenoses by far outnumber the tight focal lesions in a given coronary tree, the lesser stenoses cause more infarctions, even though high-grade stenoses have a greater individual probability of causing infarction.

Thrombosis and Atheroma Complication

Several major modes of plaque disruption provoke most coronary thrombi.⁶⁰⁻⁶² The first mechanism, accounting for some two thirds of acute myocardial infarctions, involves a fracture of the plaque's fibrous cap (**Fig. 41-13**). Another mode involves a superficial erosion of the intima (**Fig. 41-14**), accounting for at least a quarter of acute myocardial infarctions in selected referral cases of sudden cardiac death.⁶³ Superficial erosion is more frequently the underlying precipitating event in women than in men as a mechanism of coronary sudden death.⁶⁴

Plaque Rupture and Thrombosis

The rupture of the plaque's fibrous cap probably reflects an imbalance between the forces that impinge on the plaque's cap and the mechanical strength of the cap. Interstitial forms of collagen provide most of the biomechanical resistance to disruption of the fibrous cap.

Hence the metabolism of collagen probably participates in regulating the propensity of a plaque to rupture (**Fig. 41-15**). Factors that decrease collagen synthesis by SMCs can impair their ability to repair and to maintain the plaque's fibrous cap. For example, the T cell-derived cytokine interferon- γ potentially inhibits SMC collagen synthesis. On the other hand, as already noted, certain mediators released from platelet granules during activation (including TGF- β and PDGF) can increase SMC collagen synthesis, tending to reinforce the plaque's fibrous structure.

In addition to reduced de novo collagen synthesis by SMCs, increased catabolism of the extracellular matrix macromolecules that compose the fibrous cap also can contribute to weakening of this structure, rendering it susceptible to rupture and hence thrombosis. The same matrix-degrading enzymes thought to contribute to smooth muscle migration and arterial remodeling also may contribute to weakening of the fibrous cap (see **Fig. 41-15**). Macrophages in advanced human atheroma overexpress MMPs and elastolytic cathepsins, which can break down the collagen and elastin of the arterial extracellular matrix.⁶⁵ Thus the strength of the plaque's fibrous cap undergoes dynamic regulation, linking the inflammatory response in the intima with the molecular determinants of plaque stability and hence thrombotic complications of atheroma. Thin fibrous caps associate with plaque rupture, probably resulting from reduced collagen synthesis and increased degradation.

A relative lack of SMCs also characterizes plaques that have caused fatal myocardial infarctions (see **Fig. 41-13B**). As explained earlier, inflammatory mediators, both soluble and associated with the surface of T lymphocytes, can provoke programmed death of SMCs. Dropout of SMCs from regions of local inflammation within plaques probably contributes to the relative lack of SMCs at points of plaque rupture. Because these cells produce new collagen needed to repair and to maintain the matrix of the fibrous cap, the lack of SMCs may contribute to weakening of the fibrous cap and hence the propensity of that plaque to rupture.⁶⁵

Plaques that have fatally ruptured exhibit another microanatomic feature: prominent accumulation of macrophages with a large lipid pool. From a strictly biomechanical viewpoint, a large lipid pool can serve to concentrate biomechanical forces on the shoulder regions of plaques, where they frequently fracture. From a metabolic standpoint, the activated macrophage characteristic of the plaque's core region produces the cytokines and the matrix-degrading enzymes thought to regulate aspects of matrix catabolism and SMC apoptosis in turn. Apoptotic macrophages and SMCs can generate particulate tissue factor, a potential instigator of microvascular thrombosis after

spontaneous or iatrogenic plaque disruption. The success of lipid-lowering therapy in reducing the incidence of acute myocardial infarction or unstable angina in patients at risk may result from a reduced accumulation of lipid and a decrease in inflammation and plaque thrombogenicity. Animal studies and accumulated data from monitoring peripheral markers of inflammation in humans support this concept.^{62,66}

Thrombosis Due to Superficial Erosion of Plaques

The preceding section discusses the pathophysiology of rupture of the plaque's fibrous cap. The pathobiology of superficial erosion has received much less attention. In experimental atherosclerosis in the nonhuman primate, areas of endothelial loss and platelet deposition occur in more advanced plaques (see **Fig. 41-14**). In humans, superficial erosion appears

FIGURE 41-13 Examples of disrupted plaques in coronary arteries visualized by optical coherence tomography. **A**, Rupture of a fibrous cap. Arrowheads point to the intimal discontinuity; the lucent cavity below (asterisk) probably represents an ulcer containing a lipid-rich core. Some or all of the thrombogenic contents of this core may have herniated into the artery and embolized. **B**, An apparent thrombus (arrows) in a region without evident fibrous cap rupture probably represents superficial erosion. (From Jia H, Abtahian F, Aguirre AD, et al: *In vivo diagnosis of plaque erosion and calcified nodule in patients with acute coronary syndrome by intravascular optical coherence tomography*. *J Am Coll Cardiol* 62:1748, 2013.)

FIGURE 41-14 Superficial erosion of experimental atherosclerotic lesions, shown by means of scanning electron microscopy. Advanced atherosclerotic plaques can promote thrombosis by superficial erosion of the endothelial layer, exposing the blood and platelets to the subendothelial basement membrane containing collagen platelet activation and thrombosis. **A**, In the low-power view, the rent in endothelium is evident. Leukocytes (arrows) have adhered to the subendothelium, which is beginning to be covered with a carpet of platelets. **B**, The high-power view shows a field selected from the center of **A** that shows the leukocytes and platelets adherent to the sub-endothelium. **C**, A low-power histologic section through a coronary artery, thrombosed as a result of superficial erosion. L = lumen; T = thrombus. (**A, B**, From Faggiotto A, Ross R: *Studies of hypercholesterolemia in the nonhuman primate. II. Fatty streak conversion to fibrous plaque. Arteriosclerosis* 4:341, 1984. **C, D**, From Farb A, Burke AP, Tang AL, et al: *Coronary plaque erosion without rupture into a lipid core. A frequent cause of coronary thrombosis in sudden coronary death. Circulation* 93:1354, 1996.)

FIGURE 41-15 Inflammation regulates metabolism of fibrillar collagen, which may influence atherosclerotic plaque disruption. The T lymphocyte releases proinflammatory cytokines such as IFN- γ (lower left) that inhibit smooth muscle cells from producing the new collagen required to lay down the collagenous matrix of the plaque's fibrous cap, which protects the plaque from rupture. The T cell-derived cytokine CD40L stimulates mononuclear phagocytes (center) to elaborate interstitial collagenases including MMP-1, MMP-8, and MMP-13, which catalyze the initial proteolytic cleavage of the intact collagen fibril. The cleaved collagen can then undergo additional degradation by gelatinases such as MMP-9. In this way, inflammation can threaten the stability of atherosclerotic plaques and increase their tendency to rupture, thereby causing thromboses, which trigger most acute coronary syndromes. (From Libby P: *The molecular mechanisms of the thrombotic complications of atherosclerosis. J Intern Med* 263:517, 2008.)

more likely to cause fatal acute myocardial infarction in women and in persons with hypertriglyceridemia and diabetes mellitus, but the underlying molecular mechanisms remain obscure. Apoptosis of ECs could contribute to desquamation of ECs in areas of superficial erosion. Likewise, MMPs, such as certain gelatinases specialized in degrading the nonfibrillar collagen found in the basement membrane (e.g., collagen type IV), also may sever the tetherings of the EC to the subjacent basal lamina and promote their desquamation. Vasospasm of atherosclerotic coronary arteries in rabbits can promote endothelial damage, thrombosis, and myocardial infarction.⁶⁷

Most plaque disruptions do not give rise to clinically apparent coronary events. Careful pathoanatomic examination of hearts obtained from patients who have succumbed to noncardiac death has shown a surprisingly high incidence of focal plaque disruptions with limited mural thrombi. Moreover, hearts fixed immediately after explantation from persons with severe but chronic stable coronary atherosclerosis who had undergone transplantation for ischemic cardiomyopathy show similar evidence for ongoing but asymptomatic plaque disruption. Experimentally, in atherosclerotic nonhuman primates, mural platelet thrombi can complicate plaque erosions without causing arterial occlusion. Therefore repetitive cycles of plaque disruption, thrombosis in situ, and healing probably contribute to lesion evolution and plaque growth. Such episodes of thrombosis and healing constitute one type of crisis in the history of a plaque that may cause a burst of SMC proliferation, migration, and matrix synthesis (see Fig. 41-11). Plaque disruptions with healing underlie many thrombi that cause sudden death, indicating that nonocclusive thrombosis may precede the fatal event more frequently than has been previously recognized.⁶⁴ TGF- β and PDGF released from platelet granules may promote healing at the site of thrombosis by stimulating migration and collagen synthesis by SMCs, as noted earlier. Thrombin, generated at sites of mural thrombosis, potentially stimulates SMC proliferation. The “burned-out” fibrous and calcific atheroma may represent a late stage of a plaque that previously was lipid-rich with characteristics associated with rupture, but that has become fibrous and hypocellular because of a wound healing response mediated by the products of thrombosis and calcification seeded by cell death.

Diffuse and Systemic Nature of Plaque Susceptibility to Rupture and Inflammation in Atherogenesis

Studies at autopsy of atherosclerotic plaques that caused fatal thrombosis brought the notion of the so-called “vulnerable” or “high-risk” plaque to the fore. This observation stimulated many investigators to seek ways of identifying and treating such high-risk atherosclerotic lesions. Current evidence, however, suggests that more than one such high-risk plaque often resides in a given coronary tree. Moreover, the inflammation thought to characterize the so-called vulnerable plaque appears widespread.⁶⁸ Studies using various imaging modalities have underscored the multiplicity of such high-risk plaques.⁶⁹ Angiography, intravascular ultrasound, optical coherence tomography, magnetic resonance imaging, and computed tomographic angiography (among other technologies) all have shed light on the morphology of plaques that cause acute coronary syndromes.⁷⁰ These various modalities generally have found an association of lesions that cause acute manifestations (“culprit lesions”) with positive remodeling or compensatory enlargement of arteries, radiolucency, and spotty calcification.⁷¹

Several concordant lines of evidence support the systemic and diffuse nature of inflammation associated with acute coronary syndromes.⁶¹ Moreover, multiple studies have shown that various systemic markers of inflammation, such as C-reactive protein, increase in patients at risk for acute coronary syndromes (see Chapter 42). Inflammation precedes the acute coronary syndrome, as revealed by profiling of the platelet transcriptome, providing a window on gene transcription many days before the acute event. Two of the most elevated transcripts in studies comparing mRNA from platelets of patients with ST-segment elevation with that from patients with stable coronary artery disease encode proteins implicated in

inflammation.⁷² Thus a combination of imaging studies and investigations using inflammatory markers supports the diffuse and systemic nature of instability of atheromas in individuals with or at risk for acute coronary syndromes. This recognition has important therapeutic implications. In addition to appropriately deployed local revascularization strategies, affected patients also should receive systemic therapy aimed at stabilizing the usually multiple high-risk lesions that may cause recurrent events.

Thrombosis depends not only on the “solid state” of the plaque that may rupture or erode to trigger thrombosis but also on the “fluid phase” of blood that determines the consequences of a given plaque disruption⁶² (Fig. 41-16). The amount of tissue factor in the lipid core of a plaque (the solid state) can control the degree of clot formation that will ensue after disruption. The level of fibrinogen in the fluid phase of blood can influence whether a plaque disruption will cause an occlusive thrombus that can precipitate an acute ST-segment elevation myocardial infarction or yield merely a small mural thrombus. Likewise, elevated levels of inhibitors of fibrinolysis, such as plasminogen activator inhibitor 1 (PAI-1), will impede the ability of endogenous thrombolytic enzymes to limit thrombus growth or persistence. Inflammation regulates both the fluid-phase and solid-state factors delineated earlier, including tissue factor, fibrinogen, and PAI-1. This notion helps explain the links between inflammation and thrombotic complications of atherosclerosis that have emerged from laboratory and clinical investigations.

SPECIAL CASES OF ARTERIOSCLEROSIS

Restenosis after Arterial Intervention

The problems of restenosis and in-stent stenosis after percutaneous arterial intervention (see Chapter 55) represent special cases of arterial hyperplastic disease. After balloon angioplasty, luminal narrowing recurs in approximately one third of cases within 6 months. Work on the pathophysiology of restenosis after angioplasty initially focused on smooth muscle proliferation. Much of the thinking regarding the pathobiology of restenosis or in-stent stenosis depended on extension to the human situation of the results of withdrawal of an overinflated balloon or overexpanded stents in previously normal animal arteries. Study of balloon-injured rat carotid arteries permitted precise understanding of the kinetics of intimal thickening after this type of injury, but the attempts to transfer this information to human restenosis met with considerable frustration. This disparity between experimental injury of animal arteries and human restenosis is not surprising. The substrate of the animal studies was usually a normal artery rather than an atherosclerotic one, with all the attendant cellular and molecular differences highlighted earlier.

Although SMC proliferation appears to be prominent in intimal thickening following experimental arterial injury, observations of human specimens showed relatively low rates of SMC proliferation and have called into question the therapeutic targeting of this process. Moreover, intravascular ultrasound studies in humans and considerable evidence from animal experimentation suggested that a substantial proportion of the loss of luminal caliber after balloon angioplasty resulted from a constriction of the vessel from the adventitial side (negative remodeling). These observations renewed interest in adventitial inflammation, with scar formation and wound contraction as a mechanism of arterial constriction after balloon angioplasty.

The widespread use of stents refocused the restenosis problem. The process of in-stent stenosis, in contrast with restenosis after balloon angioplasty, depends uniquely on intimal thickening as opposed to negative remodeling. The stent provides a firm scaffold that prevents constriction from the adventitia. Histologic analyses reveal that a great deal of the volume of the in-stent stenotic lesion is made up of “myxomatous” tissue, comprising occasional stellate SMCs embedded in a loose and highly hydrated extracellular matrix. The introduction of stents has reduced the clinical impact of restenosis because of the technique’s effectiveness in increasing luminal diameter. Even with a considerable degree of lumen loss secondary

Determinants of Thrombosis in Coronary Atherosclerotic Plaques

FIGURE 41-16 A two-state model of atherothrombosis. The high-risk atheroma has a thin fibrous cap overlying a large lipid core that contains tissue factor-bearing macrophages. When the fibrous cap fractures, coagulation proteins in the fluid phase of blood gain access to tissue factor-associated macrophages and tissue factor-bearing microparticles derived from apoptotic cells in the solid state of the plaque. These events trigger thrombus formation on the ruptured plaque. The clinical consequences depend on the amount of tissue factor and apoptosis in the plaque's core and on the levels of fibrinogen and PAI-1 in the fluid phase of blood. The interaction of the fluid phase with the solid state will determine whether a given plaque disruption provokes a partial or transient coronary artery occlusion (that can be clinically silent or less commonly cause an episode of unstable angina) or a devastating persistent and occlusive thrombus that can precipitate an acute myocardial infarction. Inflammation regulates the thrombotic/fibrinolytic balance in both the solid state and the fluid phase, because PAI-1 and fibrinogen both are acute-phase reactants and because the inflammatory mediator CD40 ligand (CD154) induces tissue factor expression. EC = endothelial cell; PAI-1 = plasminogen activator inhibitor; SMC = smooth muscle cell; t-PA = tissue plasminogen activator; u-PA = urokinase type plasminogen activator. (From Libby P, Theroux P. Pathophysiology of coronary artery disease. *Circulation* 111:3481, 2005.)

to intimal thickening, the luminal caliber restored is sufficient to alleviate the patient's symptoms because of the excellent dilation achieved. The use of drug-eluting stents (DESs) has greatly reduced in-stent stenosis, and newer-generation DESs appear to limit the potential for augmenting late stent thrombosis associated with earlier DESs (see Chapter 55). The risk of late thrombosis after radiation brachytherapy or with stents that contain antiproliferative agents may relate to impaired endothelial healing, with attendant loss of the anticoagulant and profibrinolytic properties of the normal intimal lining (see Fig. 41-2).

Accelerated Arteriosclerosis after Transplantation

Since the advent of effective immunosuppressive therapy such as cyclosporine, the major limitation to long-term survival of cardiac allografts is the development of an accelerated form of arterial hyperplastic disease (see Chapter 28). I favor the term *arteriosclerosis* (hardening of the arteries) rather than *atherosclerosis* (gruel-hardening) to describe this process because of the inconstant association with lipids (the "gruel" in atherosclerosis). This form of arterial disease often presents a diagnostic challenge. The patient may not experience typical anginal symptoms because of posttransplantation cardiac denervation. In addition, graft coronary disease is concentric and diffuse, not only affecting the proximal epicardial coronary vessels but also penetrating smaller intramyocardial branches (Fig. 41-17). For this reason, the angiogram, well suited to visualize focal and eccentric stenoses, consistently underestimates the degree of transplantation arteriosclerosis.

In most centers, a majority of patients undergoing transplantation have atherosclerotic disease and ischemic cardiomyopathy, but a sizable minority undergo heart transplantation for idiopathic dilated cardiomyopathy and may have few (if any) risk factors for

atherosclerosis. Even in the absence of traditional risk factors, this latter group of persons share the risk for development of accelerated arteriosclerosis. This observation suggests that the pathophysiology of this form of accelerated arteriosclerosis differs from that of typical atherosclerosis.

The selective involvement of the engrafted vessels, with sparing of the host's native arteries, suggests that accelerated arteriopathy does not merely result from immunosuppressive therapy or other systemic factors in the transplantation recipient. Rather, these observations suggest that the immunologic differences between the host and recipient vessels might contribute to the pathogenesis of this disease.³⁸ Considerable evidence from both human and experimental studies currently supports this viewpoint.⁷³ ECs in the transplanted coronary arteries express histocompatibility antigens that can engender an allogeneic immune response from host T cells. The activated T cells can secrete cytokines (e.g., interferon- γ) that can augment histocompatibility gene expression, recruit leukocytes by induction of adhesion molecules, and activate macrophages to produce SMC chemoattractants and growth factors. Interruption of interferon- γ signaling can prevent experimental graft coronary disease in mice.

Thus graft arteriosclerosis represents an extreme case of immunologically driven arterial hyperplasia (Fig. 41-18) that can occur in the absence of other risk factors. At the other extreme, patients with homozygous familial hypercholesterolemia can develop fatal atherosclerosis in the first decade of life solely as a result of an elevation in LDL. Most patients with atherosclerosis fall somewhere between these two extremes. Analysis of usual atherosclerotic lesions shows evidence for a chronic immune response and lipid accumulation. Therefore, by studying the extreme cases, such as transplantation arteriopathy and familial hypercholesterolemia, one can gain insight into elements of the pathophysiology that contribute to the multifactorial form of atherosclerosis that affects the majority of patients.

Aneurysmal Disease

Atherosclerosis also produces aneurysmal disease (see Chapter 57). Why is a single disease process manifested in directionally opposite manners, for example, most commonly producing stenoses in the coronary arteries but also causing ectasia of the abdominal aorta? In particular, aneurysmal disease characteristically affects the infrarenal abdominal aorta. This region is highly prone to the development of atherosclerosis. Data from the Pathobiological Determinants of Atherosclerosis in Youth (PDAY) study show that the dorsal surface of the infrarenal abdominal aorta has a particular predilection for the development of fatty streaks and raised lesions in Americans younger than 35 years of age who succumbed for noncardiac reasons (see Fig. 41-1). Because of the absence of vasa vasorum, the relative lack of blood supply to the tunica media in this portion of the abdominal aorta might explain the regional susceptibility of this portion of the arterial tree to aneurysm formation. In addition, the lumbar lordosis of the biped human may alter the hydrodynamics of blood flow in the distal aorta, yielding flow disturbances that may promote lesion formation.

Histologic examination shows considerable distinction between occlusive atherosclerotic disease and aneurysmal disease. In typical coronary artery atherosclerosis, expansion of the intimal lesion produces stenotic lesions. The tunica media underlying the expanded

FIGURE 41-17 Comparison of typical atherosclerosis and transplantation arteriosclerosis. **Left**, Typical atherosclerosis characteristically forms an eccentric lesion with a lipid core and fibrous cap. **Right**, By contrast, the lesion of transplantation-associated accelerated arteriosclerosis characteristically exhibits a concentric intimal expansion without a clear central lipid core.

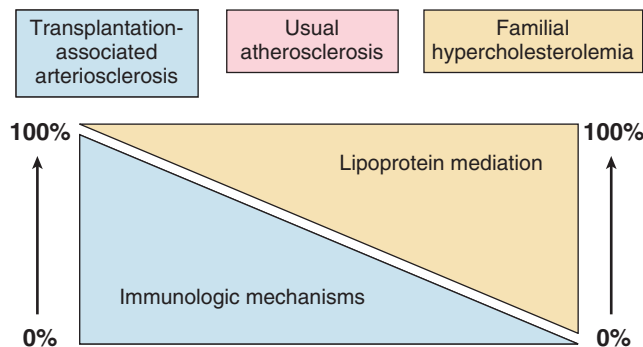

FIGURE 41-18 A multifactorial view of the pathogenesis of atherosclerosis. This diagram depicts the relative contributions of the main pathogenic mechanisms in two extreme cases of atherosclerosis. In transplantation-associated disease (*far left*), accelerated arteriosclerosis can occur in the transplanted heart in the absence of traditional coronary risk factors. This disease probably represents primarily immune-mediated arterial intimal disease. In the other extreme (*far right*) is familial hypercholesterolemia, the patient may succumb to rampant atherosclerosis in the first decade of life solely because of an elevated LDL level due to a mutation in the LDL receptor (homozygous familial hypercholesterolemia). Between these two extremes lie most cases of atherosclerosis, probably involving various mixtures of immune and inflammatory or lipoprotein-mediated disease. One can further consider that this diagram extends to a third dimension that would involve other candidate risk factors, such as homocysteine, lipoprotein(a), infection, and tobacco abuse.

intima often is thinned, but its general structure remains relatively well preserved. By contrast, transmural destruction of the arterial architecture occurs in aneurysmal disease. In particular, the usually well-defined laminar structure of the normal tunica media disappears with obliteration of the elastic laminae. The medial SMCs, usually well preserved in typical stenotic lesions, are notable for their paucity in the media of advanced aortic aneurysms.

Study of the pathophysiology that underlies these anatomic-pathologic findings has proved frustrating. Experimental aneurysm formation in animals has uncertain relevance to the clinical disease. The human specimens obtainable for analysis generally represent the late stages of this disease. Nonetheless, recent work has identified several mechanisms that may underlie the peculiar pathology of aneurysmal disease. Widespread destruction of the elastic laminae suggests a role for degradation of elastin, collagen, and other constituents of the arterial extracellular matrix. Many studies have documented overexpression of matrix-degrading proteinases, including MMPs, in human aortic aneurysm specimens. Clinical trials are

testing the hypothesis that MMP inhibitors can reduce the expansion of aneurysms. In atherosclerotic mice, angiotensin II potentiates aneurysm formation. Alterations in TGF- β signaling can predispose to aneurysm formation. Mutations in TGF- β receptors can cause arterial ectasia.¹²

Thus heightened elastolysis may explain the breakdown of the usually ordered structure of the tunica media in this disease. A slant toward T helper cell Th2 populations in aneurysmal versus occlusive disease may contribute to the overexpression of certain elastolytic enzymes.^{74,75} In addition, aortic aneurysms show evidence for considerable inflammation, particularly in the adventitia. The lymphocytes that characteristically abound on the adventitial side of aneurysmal tissue suggest that apoptosis of SMCs triggered by inflammatory mediators including soluble cytokines and Fas ligand, elaborated by these inflammatory cells, may contribute to SMC destruction and promote aneurysm formation. Although extracellular matrix degradation and SMC death also occur in sites where atherosclerosis causes stenosis, they appear to predominate in regions of aneurysm formation and to affect the tunica media much more extensively, for reasons that remain obscure.

Infection and Atherosclerosis

Interest persists in the possibility that infections may cause atherosclerosis. A considerable body of seroepidemiologic evidence supported a role for certain bacteria, notably *Chlamydia pneumoniae*, and certain viruses, notably cytomegalovirus, in the etiology of atherosclerosis. The seroepidemiologic studies have spurred a number of in vivo and in vitro experiments that have lent various degrees of support to this concept. Indeed, multiple clinical trials have not shown benefit of antibiotic therapy in secondary prevention of atherosclerotic events.⁷⁶

Several caveats apply in the evaluation of the seroepidemiologic evidence. First, confounding factors should be carefully considered. For example, smokers may have a higher incidence of bronchitis due to *C. pneumoniae*. Therefore evidence for infection with *C. pneumoniae* may merely serve as a marker for tobacco use, a known risk factor for atherosclerotic events. In addition, a strong bias favors the publication of positive studies as opposed to negative studies. Thus meta-analyses of seroepidemiologic studies may be slanted toward the positive merely because of underreporting of negative studies. Finally, atherosclerosis is a common and virtually ubiquitous disease in developed countries. Many adults have serologic evidence of previous infections with members of Herpesviridae, such as cytomegalovirus, and respiratory pathogens, such as *C. pneumoniae*. Sorting out coincidence from causality is difficult when a majority of the population studied exhibits evidence of both infection and atherosclerosis.

Although proof that bacteria or viruses can cause atherosclerosis remains elusive, infections may potentiate the action of traditional risk factors, such as hypercholesterolemia. Based on the vascular biology of atherosclerosis discussed in this chapter, several scenarios might apply. First, cells within the plaque itself may harbor infection. For example, macrophages existing in an established atherosclerotic lesion might become infected with *C. pneumoniae*, which could spur their activation and accelerate the inflammatory pathways currently believed to operate within the atherosclerotic intima. Specific microbial products, such as lipopolysaccharides, heat shock proteins, or other virulence factors, may act locally at the level of the artery wall to potentiate atherosclerosis in infected lesions. Increased focus on the intestinal microbiome supports the view that exposure of vascular cells to bacterial products such as endotoxin may not be a mere laboratory phenomenon but applies in vivo. A slight breach in the integrity of the intestinal epithelium with release of microbial danger signals could have a direct effect on vascular cells or could alter systemic risk factors by activating inflammation in visceral adipose tissue, contributing to insulin resistance and other features of the "metabolic syndrome" cluster.⁷⁷ Moreover, metabolites produced by gut microflora from dietary constituents may augment atherogenesis.⁷⁸

Extravascular infection also may potentially influence the development of atheromatous lesions and provoke their complication. For example, circulating endotoxin or cytokines produced in response to a remote infection can act locally at the level of the artery wall to promote the activation of vascular cells and of leukocytes in preexisting lesions, producing an “echo” at the level of the artery wall of a remote infection. The acute-phase response to an infection in a non-vascular site also may affect the incidence of thrombotic complications of atherosclerosis by increasing fibrinogen or plasminogen activator inhibitor or by otherwise altering the balance between coagulation and fibrinolysis. Such disturbance in the prevailing pro-thrombotic, fibrinolytic balance may critically influence whether a given plaque disruption will produce a clinically inapparent transient or nonocclusive thrombus or sustained and occlusive thrombi that could cause an acute coronary event.

Acute infections also can produce hemodynamic alterations that could trigger coronary events. For example, the tachycardia and increased metabolic demands of fever can augment the oxygen requirements of the heart, precipitating ischemia in an otherwise compensated individual.

These various scenarios illustrate how infectious processes, either local in the atheroma or extravascular, may aggravate atherogenesis, particularly in preexisting lesions or in concert with traditional risk factors.

RETHINKING CORE APPROACHES TO PRIMARY PREVENTION

For almost half a century, interventions to reduce the risk of heart attack and stroke among persons without known heart disease have been implemented largely using a two-step process based on absolute risk. First, using a global risk-estimating algorithm such as the Framingham risk score, the Reynolds risk score, or the European Systematic Coronary Risk Evaluation (SCORE),¹ physicians have stratified patients who are candidates for primary prevention into lower-, intermediate-, and higher-risk subgroups, typically calculated over a 10-year time frame. Then, guidelines based on such stratification have traditionally targeted lifestyle interventions to those persons at "lower" and "intermediate" risk while limiting more aggressive pharmacologic interventions (such as statin therapy) to those with "higher" risk profiles.

Until recently, it was assumed that such a risk-based triage system would distribute primary prevention services efficiently. After all, if the relative benefit of a preventive intervention is similar across all levels of risk, then the greatest absolute benefit will occur among persons with the highest absolute risk. Furthermore, treatment allocation on the basis of high global risk should maximize the benefits of intervention (by targeting those at greatest need) while reducing potential adverse actions and cost (by avoiding exposure to treatment among those with the least need).

Currently, however, some in the preventive cardiology community have challenged these long-held beliefs, and have proposed instead that preventive services should be allocated on the basis of proven randomized trial data—that is, "what works?" and "in whom?"—rather than on the basis of an arbitrary scaling of global risk.² This reconsideration has major implications for how we think about preventive cardiovascular care as well as for guidelines, for the design of future clinical trials, and for emerging preventive concepts such as the "polypill" and broad use of effective generic drugs by prescription or over the counter, independent of individual risk assessment.

Consider the situation for statin therapy. Ten years ago, the volume of trial data on the efficacy of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors as an adjunct to diet, exercise, and smoking cessation in specific patient groups was limited, safety data were uncertain, and the cost of treatment was relatively high, particularly for higher-potency statin agents. Thus, facing uncertainty, those

writing older guidelines chose appropriately to model the potential benefits of lipid-lowering treatment on the basis of epidemiologic risk scales, even though those scores had never themselves undergone randomized evaluation for improvement of outcomes, nor were they used as trial enrollment criteria.

Unfortunately, this system of drug allocation based on epidemiologic modeling rather than completed trials has substantive limitations. First, smoking and hypertension often drive high estimates of global risk, yet the interventions of choice should be smoking cessation and blood pressure reduction rather than reflexive prescription of lipid-lowering therapy. Second, risk prediction models often have proved inadequate in terms of discrimination and calibration in specific patient groups such as ethnic minorities and women. Third, on a population basis, the vast majority of future vascular events occur in persons with intermediate or low 10-year risk estimates, so limiting intervention only to those with highest absolute risk misses large opportunities for prevention. Concepts of lifetime risk suggest that those patients with low 10-year risks often are among those with the highest long-term event rates, for whom early interventions could prove most effective.³ For these and other reasons, many clinicians do not use global risk algorithms routinely.

Most problematic, however, results of multiple randomized trials completed since 2005 do not support the notion that statin therapy has constant relative benefits across all risk groups, yet this assumption remains the fundamental justification for arguments to base therapy on absolute risk. Consider the CORONA (Controlled Rosuvastatin Multinational Trial in Heart Failure), AURORA (A Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: An Assessment of Survival and Cardiovascular Events), 4D (German Diabetes and Dialysis Study), and GISSI-HF (Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiaca—Heart Failure) trials, which in total included 13,613 patients and were reported between 2005 and 2009.⁴⁻⁷ All four of these well-conducted trials enrolled high-absolute-risk patients who achieved large low-density lipoprotein (LDL) cholesterol reductions with statin therapy. Yet none showed significant clinical benefit.

Consider further the JUPITER (Justification for the Use of Statin in Prevention: An Intervention Trial Evaluating Rosuvastatin), AFCAPS/TextCAPS (Air Force/Texas Coronary Atherosclerosis Prevention Study), and MEGA (Management of Elevated Cholesterol in the

Primary Prevention Group of Adult Japanese) trials that included 32,621 primary prevention patients and were published between 1998 and 2008.⁸⁻¹⁰ These three trials enrolled low-absolute-risk patients, most of whom would not qualify for statin therapy under any current guideline issued in the United States or Europe. Yet each showed marked benefit of statin therapy. Indeed, these three trials demonstrated the greatest relative risk reductions ever achieved with statin therapy.

Taken together, these seven trials present a major challenge to the simplistic idea that absolute risk alone can direct clinically effective allocation of statin therapy. Why then continue to recommend that statins be prescribed on the basis of an epidemiologic calculation of absolute risk? Why not allocate statins instead to patient subgroups proven in clinical trials to benefit from them? A principled, evidence-based interpretation of these recent trials would be not to use statins among patients with renal failure (4D, AURORA) or heart failure (CORONA, GISSI-HF), but to use statins aggressively in primary prevention among those with elevated LDL cholesterol (MEGA), low high-density lipoprotein (HDL) cholesterol (AFCAPS/TextCAPS), or elevated high-sensitivity C-reactive protein (hsCRP) (JUPITER).

WHAT WORKS AND IN WHOM? A SIMPLE EVIDENCE-BASED ALTERNATIVE TO THE PREVENTION OF CARDIOVASCULAR DISEASE

As just described, few if any of the basic justifications for a “risk-based” approach to statin therapy remain relevant at present. Data on safety now abound, and the evidence base has established that benefits of statin therapy on myocardial infarction (MI), stroke, revascularization procedures, and cardiovascular death outweigh the risks even for those at the lower end of the absolute vascular risk spectrum. This conclusion remains valid even after the modest but statistically significant hazard for diabetes associated with statin use in benefit-to-risk calculations is taken into account.¹¹ Second, almost all statin agents are now off patent, and the cost of treatment has declined dramatically. Third, the cardiovascular community currently has abundant data from many large-scale, randomized, placebo-controlled trials that cover a wide range of patient groups so that trial data may be directly applied to clinical care without need for epidemiologic extrapolation.¹²

In view of the current abundance of data, a simple evidence-based guideline for statin therapy using the concepts of “what works?” and “in whom?” from completed randomized trials can be written without need for complex data modeling. As an example of this emerging approach, preventive cardiologists in the United States, Canada, and Europe have suggested the following list of five recommendations as a simple, easily understood guideline for the use of statin therapy in the prevention of cardiovascular disease that avoids controversy because it is based soundly on trial data^{13,14}:

1. On this basis of high-quality randomized clinical trial data, statin therapy should be used as an adjunct to diet, exercise, and smoking cessation for secondary prevention patients with a previous history of MI, stroke, or clinically apparent atherosclerosis (4S [Scandinavian Simvastatin Survival Study], HPS [Heart Protection Study], CARE [Cholesterol And Recurrent Events], LIPID [Long-Term Intervention with Pravastatin in Ischaemic Disease]).
2. On the basis of high-quality randomized trial data, statin therapy can be considered as an adjunct to diet, exercise, and smoking cessation in the setting of primary prevention for those aged 50 and over with either diabetes (CARDS [Collaborative Atorvastatin Diabetes Study]), elevated LDL cholesterol (WOSCOPS [West of Scotland Coronary Prevention Study], MEGA), low HDL cholesterol (AFCAPS), or elevated hsCRP (JUPITER). To improve relative efficiency and cost-effectiveness, physicians may elect to limit statin prescription to the above groups who also have at least one additional risk factor such as hypertension or smoking. For patients who do not meet these criteria, physicians may consider issues such as genetic predisposition or a strong family history of premature coronary disease when making decisions for individual

patients at different ages in primary prevention. For some of these patients, such as those suspected of having familial hyperlipidemia, referral to lipid or atherosclerosis specialists may be useful for considerations of secondary testing and potential use of alternative or additional lipid-lowering therapies.

3. On the basis of high-quality randomized trial data, when prescribing statin therapy, physicians should seek to maximize the intensity of treatment and then focus efforts on compliance and long-term adherence (PROVE-IT [Pravastatin or Atorvastatin Evaluation and Infection Therapy], TNT [Treating to New Targets], IDEAL [Incremental Decrease in Clinical Endpoints Through Aggressive Lipid Lowering]). Accordingly, the target dose for an individual patient should be selected as a dose close to or at the highest level the individual patient tolerates without side effects.
4. On the basis of high-quality randomized trial data, the use of nonstatin lipid-lowering agents for monotherapy or in combination with a statin should be limited during the wait for evidence that such an approach further reduces cardiovascular event rates in specific patient groups (AIM-HIGH [Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides: Impact on Global Health Outcomes], HPS2-THRIVE [Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events], ACCORD [Action to Control Cardiovascular Risk in Diabetes], FIELD [Fenofibrate Intervention and Event Lowering in Diabetes]). In some cases this approach may be suboptimal, such as in patients who demonstrate statin intolerance or have familial hyperlipidemia and exceptionally high LDL cholesterol, or who have a risk of pancreatitis (see Chapter 45). Such patients can benefit from secondary evaluation by lipid specialists.
5. A guideline based on trial evidence (to determine what works) and on trial entry criteria (to ascertain in whom) is simple, practical, and consistent with evidence-based principles and should therefore result in broad clinical acceptance. New advances in prevention should be incorporated into guidelines as quickly as possible. Thus, if data on new agents demonstrate evidence of event reduction superior to that achieved with statin therapy alone, evidence of event reduction among those who are statin-intolerant, or evidence of incremental event reduction as an adjunct to statin therapy, rapid updates to guidelines should address such important advances. The Guidelines section that follows this chapter discusses the 2013 ACC/AHA risk assessment and lipid management guidelines.

MERGING EPIDEMIOLOGY AND RANDOMIZED TRIAL EVIDENCE: WHY MEASURE RISK FACTORS?

This chapter reviews the epidemiologic and clinical trial evidence underlying risk markers and interventions to reduce atherothrombotic risk in three parts. The next section describes the conventional risk factors of smoking, hypertension, hyperlipidemia, and insulin resistance and diabetes, as well as general strategies for reducing risk related to these disorders. This section explores some of the issues and controversy surrounding the concept of the “metabolic syndrome.” It also reviews evidence describing the use of low-dose aspirin in primary prevention and briefly discusses the conceptual basis for the “polypill.”

Not all coronary events occur in people with multiple traditional risk factors, however, and in some patients, abnormalities of inflammation, hemostasis, and/or thrombosis appear to contribute decisively. In particular, almost half of all MIs and strokes occur among persons without hyperlipidemia. Thus, subsequent to the section on conventional risk factors, another section reviews atherothrombotic risk markers, including hsCRP and other markers of inflammation (such as IL-1, IL-6, fibrinogen, and lipoprotein-associated phospholipase A₂ [Lp-PLA₂], as well as homocysteine and lipoprotein(a) [Lp(a)]). In each case, evidence is presented that describes whether these novel risk indicators add to risk prediction over and above that

for conventional factors (see also Chapter 10). This section also reviews the use of hsCRP as part of the Reynolds risk score to evaluate global risk more effectively, further delineate the metabolic syndrome, and improve targeting of statin therapy. Also addressed is the use of direct plaque imaging as a method of risk detection; emerging concepts in the use of genetic biomarkers to help elucidate vascular risk and target novel therapies also are presented.

The final section of the chapter addresses a series of environmental exposures and behavioral issues that have major impact on vascular health. This section reviews mental stress and depression and cardiovascular risk, as well as issues of diet, dietary supplements, obesity, exercise, and weight loss. This final section also reviews current evidence supporting moderate alcohol use, controversies surrounding postmenopausal estrogen, and issues of community-based and multiple risk factor intervention programs.

With the exception of glucose intolerance and obesity, the prevalence of most cardiovascular risk factors has declined in the United States over the past 40 years. These favorable trends suggest that interventions to reduce risk can be highly effective when applied in appropriate settings, as evidenced not only by reductions in coronary disease but also by reductions in stroke. Prevention on an international scale is thus a feasible goal. Therefore targeting risk reduction by lifestyle modification and with proven medical therapies seems to be a sensible primary goal for outpatient preventive cardiovascular practice.

Each of the following sections begins by focusing on the epidemiologic evidence linking the specific biomarker, exposure, or behavior to subsequent vascular risk. Then, in the spirit of “what works?” and “in whom?”, the randomized clinical trial evidence that supports modification of each risk marker is reviewed whenever possible. Chapter 44 takes a similar approach to the management of hypertension. In the setting of primary prevention, it is important to recognize that physicians do not measure biomarkers simply to predict risk. Rather, they do so to target therapy better and improve the lives of their patients. Thus, when considering the use of any biomarker for cardiovascular risk prediction in primary prevention, thoughtful clinicians should insist that two fundamental questions be answered affirmatively (see also Chapter 10): First, is there clear evidence that the biomarker of interest predicts future cardiovascular events independent of other risk markers? Second, is there clear evidence that persons identified by the biomarker of interest benefit from a therapy they otherwise would not have received?

As described in this chapter, on the basis of current data, no imaging biomarker can answer these questions affirmatively, nor can measurement of a variety of plasma biomarkers such as Lp(a), homocysteine, or triglycerides. For cholesterol and for hsCRP, however, the answer to both of these questions is “yes,” because randomized, placebo-controlled trials have shown that patients identified by either of these biomarkers markedly benefit from statin therapy. These findings are of particular pathophysiologic interest in the modern view of atherothrombosis as resulting from interaction of hyperlipidemia and inflammation to initiate and accelerate all phases of the disease process (see also Chapter 41).¹⁵ Supporting this view, recent experimental work has suggested that the earliest deposition of cholesterol crystals triggers the interleukin-1-beta (IL-1 β)-activating inflammatory response, thus providing a key link between lipids, inflammation, and vascular disease.¹⁶

CONVENTIONAL RISK MARKERS AND THEIR INTERVENTIONS

Smoking

Other than advanced age, smoking remains the single most important risk factor for coronary artery disease. According to the 2010 Surgeon General's Report¹⁷ cigarette consumption is the leading preventable cause of death and disease in the United States, accounting for approximately 443,000 deaths, or almost one of every five U.S. deaths, from smoking-related illnesses each year. An estimated 49,000 of

these smoking-related deaths are the result of secondhand smoke exposure. Moreover, smoking has been estimated to cost the United States \$96 billion in direct medical expenses and \$97 billion in lost productivity annually.¹⁸

Smokers lose at least one decade of life expectancy, as compared with never-smokers.¹⁹ The risk of death from cigarette smoking continues to increase among women and the increased risks are now nearly identical for men and women.²⁰ Compared with nonsmokers, smoking increases the risk of both coronary heart disease and stroke two- to fourfold. Ischemic heart disease underlies 35% to 40% of all smoking-related deaths, with an additional 8% attributable to secondhand smoke exposure. Cigarette smoking can promote vasoconstriction, resulting in a greater risk of developing symptomatic peripheral vascular disease and abdominal aortic aneurysm among smokers than nonsmokers. Secondhand smoke exposure also is associated with heart disease in nonsmoking adults. Nonsmokers exposed to secondhand smoke at home or work increase their heart disease risk by 25% to 30%. Breathing secondhand smoke has immediate harmful effects on the cardiovascular system that can increase the risk of heart attack, especially among those who already have heart disease.

From a prevalence of adult smoking of 43% in 1964, the prevalence of adults smoking cigarettes fell to 19% in 2011,²¹ 21.6% among males and 16.5% among females. Prevalence was lowest among non-Hispanic Asians (9.9%) and highest among non-Hispanic American Indians and Alaska natives (31.5%). By age, prevalence was lowest among adults 65 years of age and older (7.9%) and highest among those 25 to 44 years of age (22.1%). Prevalence was higher among adults living below the federal poverty level (29.0%) and among those reporting a disability (35.4%).²²

The U.S. Healthy People 2020 initiative aims to reduce the national prevalence of cigarette smoking among adults to a target of 12%. The period 2005 to 2011 saw only a slight overall decline in current smoking prevalence, but the number of cigarettes smoked per day declined, as did the prevalence of current smoking occurring among adults 18 to 24 years of age. Among daily smokers overall, the proportion who smoked 30 cigarettes or more per day declined significantly from 12.6% in 2005 to 9.1% in 2011. This drop did not result from smoking cessation, however, because the proportion smoking 1 to 9 cigarettes per day increased significantly. For adults 18 to 24 years of age, current smoking prevalence declined from 24.4% to 18.9%. This age group, which had the highest prevalence in 2005, now has the lowest of any group younger than 65 years of age (Fig. 42-1).

Consumption of tobacco products is increasing globally with the greatest increase in the developing world. Tobacco kills almost 6 million people each year, more than 5 million of whom are users and ex-users, and more than 600,000 of whom are nonsmokers exposed to secondhand smoke. This annual death toll could rise to more than 8 million by 2030.^{23,24} More than 80% of these deaths will be in

FIGURE 42-1 Percentage of adults aged 18 years and older self-reported as current smokers, by age group. National Health Interview Survey, United States, 2005 to 2011. (From Centers for Disease Control and Prevention (CDC): Current cigarette smoking among adults—United States, 2011. *MMWR Morb Mortal Wkly Rep* 61:889, 2012.)

low-income and middle-income countries. Tobacco caused 100 million deaths in the 20th century, and if current trends continue, it will cause up to 1 billion deaths in the 21st century.

Landmark studies in the early 1950s first reported strong positive associations between cigarette smoke exposure and coronary heart disease. Over the next 50 years, an exceptionally consistent series of prospective studies documented the effects of smoking on coronary risk. The 1964 Surgeon General's report reaffirmed the epidemiologic correlation, and by 1983 the Surgeon General had firmly established cigarette smoking as the leading avoidable cause of cardiovascular disease. Based largely on studies among men, the 1989 Surgeon General's report showed that smoking doubles the incidence of coronary heart disease and increases coronary heart disease-related mortality by 50%, and that these risks increase with age and the number of cigarettes smoked. "Light" levels of smoking have a major impact on MI and all-cause mortality, even among smokers who do not report inhalation. In addition to MI, cigarette consumption directly relates to increased rates of sudden death, aortic aneurysm formation, symptomatic peripheral vascular disease, and ischemic stroke. Prospective evidence has linked cigarette consumption to an elevated risk of hemorrhagic stroke, including intracranial hemorrhage and subarachnoid hemorrhage, again in a dose-response manner. Continued smoking is also a major risk factor for recurrent MI. Even among nonsmokers, inhaled smoke, whether from passive exposure or from cigar or pipe consumption, increases coronary risk. Passive smoking exposure can cause endothelial vasodilator dysfunction in the coronary circulation as well as increased bronchial responsiveness and concomitant pulmonary dysfunction. There is no safe level of exposure to secondhand tobacco smoke.

Women incur similar increases in the relative risk for coronary heart disease. Smoking acts synergistically with oral contraceptive agents, placing younger women taking these agents at even higher relative risk. Because of adverse synergy with oral contraceptives, young female smokers who take oral contraceptives have particularly elevated risks for premature coronary disease and stroke. Smoking is especially hazardous for women with diabetes.

Beyond acute unfavorable effects on blood pressure and sympathetic tone and a reduction in myocardial oxygen supply, smoking contributes to the pathogenesis of atherothrombosis by several other mechanisms. Long-term smoking may enhance oxidation of LDL cholesterol and impair endothelium-dependent coronary artery vasodilation. This latter effect has been linked to dysfunctional endothelial nitric oxide biosynthesis with chronic as well as acute cigarette consumption. In addition, smoking has adverse hemostatic and inflammatory effects, including increases in levels of C-reactive protein (CRP), soluble intercellular adhesion molecule-1 (ICAM-1), fibrinogen, and homocysteine. Additionally, smoking is associated with spontaneous platelet aggregation, increased monocyte adhesion to endothelial cells, and adverse alterations in endothelium-derived fibrinolytic and antithrombotic factors, including tissue-type plasminogen activator and tissue pathway factor inhibitor. Compared with nonsmokers, smokers have an increased prevalence of coronary spasm and a reduced threshold for ventricular arrhythmias. Accumulating evidence has suggested that insulin resistance represents an additional mechanistic link between smoking and premature atherosclerosis.

Interventions for Smoking Cessation

Cessation of cigarette consumption overwhelmingly remains the single most important intervention in preventive cardiology. Although data from large-scale, randomized trials concerning the risk reduction associated with smoking cessation are limited, observational studies consistently demonstrate the clear benefits of smoking cessation. Smokers who quit reduce their excess risk of a coronary event by 50% within the first 2 years after cessation, with much of this benefit seen even within the first few months. Coronary heart disease risk falls substantially within 1 to 2 years of cessation, with the risk in former smokers approaching that in never-smokers after 3 to 5 years. Similarly, the risk of stroke decreases steadily after smoking cessation, with former smokers having the same stroke risk as in nonsmokers after 5 to 15 years. This benefit is much more rapidly

FIGURE 42-2 Risks of death for continuing smokers and those who quit, according to age at time of cessation. (From Jha P, Ramasundarahettige C, Landsman V, et al: 21st-century hazards of smoking and benefits of cessation in the United States. *N Engl J Med* 368:341, 2013.)

realized than that seen with smoking and lung cancer. Moreover, the beneficial effect on coronary heart disease and mortality rates are seen even among elderly persons, supporting the idea that it is never too late to quit smoking for decreasing CHD coronary heart disease-associated risks (Fig. 42-2). These risk reductions equal or exceed those for other secondary prevention interventions that have received more attention from physicians and the pharmaceutical industry, including the use of aspirin, statins, beta-adrenergic blocking agents, and angiotensin-converting enzyme (ACE) inhibitors.

Studies show that few people understand the specific health risks of tobacco use. Yet, among smokers who are aware of the dangers, most want to quit. Overall, approximately 69% of smokers in the United States want to quit completely,²⁵ and in 2011, of current smokers and those who had quit during the preceding year, 51.8% had made a quit attempt for more than one day during the preceding year. Poor patient understanding of the importance of smoking cessation continues, particularly in the developing world. For example, a 2009 survey in China showed that only 37% of smokers knew that smoking caused coronary heart disease and only 17% knew it caused stroke. Substantial misunderstanding also surrounds, for example, the observation that smoking predicts better outcome after various reperfusion strategies (the so-called smoker's paradox). Some researchers have regarded this effect as a "benefit" of smoking, but it probably reflects that smokers tend to undergo such procedures at a much younger age and hence have on average lower rates of comorbid illness.

Clinical practice guidelines recognize tobacco dependence as a chronic condition that often requires repeated interventions. Nevertheless, effective evidence-based treatments do exist. Multiple attempts may be necessary, but smokers can and do quit smoking. In fact, since 2002, the number of former smokers has exceeded the number of current smokers.²⁵
